Note to the Reader

The National Research Council (NRC) has not established standards for nutritional products fed to birds; therefore, claims of nutritional completeness can not legally or ethically be made. Human medical textbooks and those of domestic animals have established normal laboratory values, recommended treatment regimes and nutritional disease states — all based on individuals meeting minimum standards of nutrition. These are not available in avian medicine.

The above parties shall not be liable to any party for any damages, nor considered negligent for any misstatement or error obtained in this text.

Foreword

If you do something long enough, you will eventually be able to step back and observe the real progress that has been made in your field of endeavor. After almost thirty years of avian practice I am amazed and gratified how far we have come. When I started practicing in 1976, in a given year, it was an easy task to read every thing published about clinical avian medicine. That has obviously and dramatically changed. The formation of the Association of Avian Veterinarians increased the generation of published materials considerably. Over the years, as each major text neared the publication date, an excitement was generated. Greg Harrison, with the assistance of co-editors Linda Harrison and Branson Ritchie with previous texts, and Teresa Lightfoot with Clinical Avian Medicine, has learned to distill the massive amount of material into a manageably useful and cohesive text.

Clinical Avian Medicine is predominantly written by clinicians for clinicians with a wonderful degree of clinical relevance. The number of high quality color photos inserted into the body of the text makes it easy to follow the ideas being presented. Thank you to doctors Harrison and Lightfoot and the fifty international authors for their hard work and perseverance in generating this most current and comprehensive avian medical reference text.

Donald W. Zantop, DVM, Diplomate American Board of Veterinary Practitioners (Avian) Fallston Veterinary Clinic, Fallston, Maryland

Preface

he future of avian medicine and stewardship is increasingly bright. Importation of wild-caught birds has been largely curtailed, and the vestiges of unethical (yet legal) loopholes as well as illegal venues for smuggling are being actively and more effectively opposed.

With the cessation of mass importation, along with vastly improved nutritional provisions, increased diagnostic and therapeutic techniques and a better understanding of the emotional needs of our pet birds, we are privileged to observe the first generations of captive-born psittacines that may survive to attain their optimal quality and length of life.

Clinical Avian Medicine offers knowledge gleaned from years of clinical experience, combined with cutting edge research. New methods of prevention, diagnosis and treatment of various diseases are included in the areas of virology, neoplasia, dermatology, neurology, necropsy techniques, hepatic disease, pain management, behavior, soft tissue and orthopedic surgery, anesthesia, endoscopy, reproductive disorders, nephrology, hematology, biochemistry, endocrinology, gastroenterology, and therapeutics. Novel topics such as low-risk (i.e., environmentally safe) pest control and integrative (alternative) avian medicine are provided. The approaches and coverage of all these topics by contributing authors are both enlightening and readily applicable to clinical practice.

Anecdotal, yet often invaluable, clinical information regarding avian disease syndromes, treatment, husbandry and nutrition are included in Clinical Avian Medicine. The exclusion of these essentials would be an impediment to the practitioner searching for information to provide treatment for his or her avian patient. Anecdotal reports can create concern with efficacy and safety if not appropriately identified. Therefore, throughout this text, we have attempted to indicate the source of the stated information, allowing the individual veterinarian to determine its applicability. Unarguably, strict scientific methods are needed to document the validity of diagnostic and treatment protocols. Yet we must not squelch the introduction of innovative and potentially life-saving techniques in clinical practice due to delays in the completion of scientific validation. Our duty as authors and editors is to present the facts as they currently stand. We believe this availability of information has the potential to enhance the quality of avian medicine, surgery and husbandry when placed in the discriminating hands of veterinary practitioners.

Greg J. Harrison, DVM, Diplomate Emeritus American Board of Veterinary Practitioners (Avian), Diplomate European College of Avian Medicine and Surgery (n.p.)

Teresa L. Lightfoot, DVM, Diplomate American Board of Veterinary Practitioners (Avian)

Vision

he vision of clinical avian practice as stated in the Preface mirrors the history and achievements of Dr. Greg Harrison. This book is first, last and foremost, the result of his lifetime dedication to avian medicine and stewardship.

When Dr. Harrison began the practice of avian medicine in the 1970's, he was one of a very few individuals in this field. Nearly all of the accepted "facts" in avian medicine were extrapolated (correctly or incorrectly) from companion animal medicine or poultry science. Dr. Harrison's early work precipitated the subsequent exponential increase in avian medical and surgical innovations throughout the following three decades. The discoveries and improvements in avian endoscopic techniques, microsurgery, radiosurgical modifications and applications, and a multitude of other current standard avian therapies are the direct result of his early work in these fields.

The publication in 1986 of the textbook, Clinical Avian Medicine and Surgery (Harrison and Harrison), provided practitioners with a much needed avian veterinary reference text. Throughout the development of that book, Dr. Harrison enlisted colleagues within the USA and abroad, involving some of the foremost authorities in this burgeoning field. The contributions of these authors, combined with Dr. Harrison's vast experience (and due in no small part to Linda Harrison's unsurpassed organizational and editorial skills), created a text with a depth of knowledge and information invaluable and previously unavailable to veterinarians in avian practice.

This has been Dr. Harrison's modus operandi throughout his career: to put forth ideas, solicit input and encourage innovation in others, and to listen open-mindedly to alternative theories. Dr. Harrison has consistently walked the difficult line between improving the application of current techniques, while seeking alternative treatments and more fundamental data.

In recent years, Dr. Harrison has dedicated his time and energies to preventive avian medicine, specifically in the area of nutrition. The outcome of this commitment has improved the health, quality and length of life of untold numbers of beloved pet birds.

As is common in innovative persons of all fields, Dr. Harrison's intense focus and drive have created ardent followers and admirers, as well as skeptics. It is again to his credit that both reactions are welcome. Advancements in avian medicine will be accelerated by those whose research validates Dr. Harrison's hypotheses, and by those whose work may contradict various theories. Within Clinical Avian Medicine, Dr. Harrison's third major avian text, the reader will encounter this broad perspective in the presentation of contrasting ideas presented by various authors.

Greg Harrison has been my role model, teacher, mentor and friend. I have been and will remain awed by him. The world of avian veterinary medicine and the world in general is a better place thanks to his contributions and his presence among us. This publication is a reflection of his life's commitment.

Teresa L. Lightfoot, DVM, Diplomate American Board of Veterinary Practitioners (Avian)

Acknowledgements

ny undertaking that involves 50 authors is touched by many others, all of whom, unfortunately, may not be mentioned. So for all those who contributed in any way, I thank you. I offer deep appreciation to all the authors for their patience and tenacity in repeatedly revisiting and reworking material to create this exceptional text.

Stormy and Paul Hudelson were very supportive, reviewing all and revising much of the text. Patty Wolf was there for every chapter over and over. Vanessa Rolfe for doing a final read through. Heather Bowles, Lori Harrison, Jack Kottwitz, Michael Lierz, Michael Pees and Michael Stanford stepped up to work on subjects that offered challenges late in the process and came through in rapid fashion.

We welcome the breakthrough contributions in this text of Debra McDonald, Robert Ness, Diana Post, Susan Friedman, Liz Wilson, Phoebe Greene Linden, Heather Bowles, Peter Sandmeier and Peter Coutteel.

To our contributors whose first language is not English, including Espen Odberg, Michael Lierz, Michael Pees, Peter Sandmeier, Manfred Hochleithner, Claudia Hochleithner, Jan Hooimeijer, Marcellus Bürkle, Peter Coutteel, Maria-Elisabeth Krautwald-Junghanns, Jens Straub, Lorenzo Crosta, and Linda Timossi: the extra skill and effort required to write in a non-native language is appreciated and admired.

Teresa Lightfoot made the whole process possible. Her talent, brilliance, humor and tenacity were my saving graces. I love her beyond words. Teresa enrolled the follow reviewers: Keeley McNeal, DVM; Lisa Teske, DVM; Krysta Deitz, DVM; Benjamin Welbourne, DVM; Hugues Lacoste, DVM; Raimon Duran-Struuck, DVM; Lisa Dixon, DVM; Valerie Sadler, DVM, Diplomate ACVR; Neil Shaw, DVM, Dipl ACVIM; John Meeks, DVM, Dipl ACVIM (Neurology); Tracy LaDue, DVM, Dipl ACVIM (Oncology), Dipl ACVR (Radiation Oncology); Mark Levy, DVM, Dipl ACVS; Eric Mears, DVM, Dipl ACVIM; Amy Benedict, CVT; Brenda Fulcher, CVT; Lee Burstiner, DVM, Dipl ABVP. Teresa also wishes to thank Florida Veterinary Specialists for the latitude and attitude to tap the knowledge and experience of the above individuals, and most of all, never-ending thanks to her husband, Chris Lane — for everything.

Nigel Harcourt-Brown is acknowledged for his art work and review of portions of the text. Additional reviewers to whom we are grateful are: David Rupiper, DVM; Jürgen P. Schumacher, Dr med vet, Dipl ACZM; and Rebecca E. Gompf, DVM, MS, Dipl ACVIM (Cardiology). Thanks to Dr. Carolyn Cray for contributions of the University of Miami to hematology and chemistry reference ranges. To others who reviewed material without acknowledgement, I offer my thanks.

Thanks to Mimi Walling for her beautiful bird photos, to Scott Echols for the use of his surgery photos and to the following for their photographic support: Auckland Zoo, E. Alberti, Lucy Bartlett, Peter Helmer, Chris Griffin, Nancy Boedeker, Carol Canny, Friedrich Janeczek, Judy St. Ledger, Eduardo Nycander, Drury Reavill, Nico Schoemaker, Michael Walsh and Don Zantop. Special thanks to Jean Coffinberry for promotional and cover concepts and to Ray Kersey, Chris Lane and Friedrich Janeczek for cover and presentation ideas.

Thank you to Tanya Harrison-Coffinberry for assistance with the organizational and financial management, production, legal issues and sale of this work. I appreciate the clients of The Bird Hospital and Harrison's Bird Foods who helped create a need for this information in the veterinary field.

My love and gratitude to Linda Harrison for encouraging me to spread my own wings with this book. There is no greater communicator of practical veterinary information than you, Linda.

Greg J. Harrison, DVM, Diplomate Emeritus American Board of Veterinary Practitioners (Avian), Diplomate European College of Avian Medicine and Surgery (n.p.)

Clinical Practice

GREG J. HARRISON, DVM, Dipl ABVP-Avian, Dipl ECAMS; GWEN B. FLINCHUM, BS, MS, DVM

Avian medicine has seen dramatic growth and development over the past several years. Veterinarians who wish to incorporate avian medicine into their practices now have numerous resources available to help them get started. The Association of Avian Veterinarians (AAV) is currently the most recognized avian veterinary professional organization in the United States, Europe and Australia. AAV national conferences provide veterinarians opportunities to share information and advice, along with programs that reveal the latest innovations in avian medicine. Other organizations in the USA include the American Federation of Aviculture, Mid-Atlantic States Association of Avian Veterinarians and statewide professional associations. The European Association of Avian Veterinarians meets every other year on the odd years. The Australian Committee of the AAV (AAVAC) meets yearly (see Table 1.1).

Education

There are numerous journals and educational materials that provide information about avian medicine. The AAV's Journal of Avian Medicine and Surgery is an international journal that provides information on the medicine and surgery of captive and wild birds and publishes scientific articles, book reviews and information regarding upcoming AAV meetings in its accompanying Newsletter. There are other resources listed in Tables 1.2 and 1.3.

Information sharing with veterinary colleagues is also available on the Internet. Forums such as Veterinary Information Network, Avian Medicine On-Line and Exotic DVM Readers' Forum (see Table 1.2) allow veterinarians from all over the world to communicate directly concerning their cases and experiences.

Fig 1.1a | A veterinary clinic's heart is its staff, who ideally are devoted, dependable, friendly, compatible and committed to patient care, service and hospital quality from floors and plants to attire. From record keeping to honesty and controlling costs, a veterinarian's dream can come true if everyone works at these goals and the work is made enjoyable.

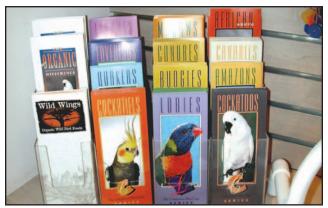

Fig 1.1c | Educating the public is the goal of a good staff. Brochures, newsletters from the clinic or product distributors, web sites, clinic-sponsored classes and guest lectures all contribute to client education.

For those veterinarians who are interested in specializing in avian medicine, The American Board of Veterinary Practitioners (ABVP) has approved residency programs leading to board certification. Alternately, experienced practitioners may apply for ABVP-Avian certification without completing a residency. In either case, the current procedure for becoming a Diplomate of ABVP-Avian Practice includes writing case studies, passing rigorous written and practical examinations, as well as satisfying other required criteria. A similar but more academically oriented credentialing system has been established in Europe and is called the European College of Avian Medicine and Surgery (ECAMS).

KNOWLEDGE AND EXPERIENCE

The first challenge is to acquire the knowledge and experience necessary to practice avian medicine in a manner on par with other branches of veterinary medicine. One needs to study the available reference materials, including the journals and proceedings from the professional organizations listed in Table 1.1. Attending

Fig 1.1b | Educating one's self and staff is much easier with access to current textbooks, references, newsletters, brochures and CDs!

meetings of these organizations will provide opportunity for hands-on experience via wet lab attendance to improve one's practical skill, and direct interaction with others in avian veterinary medicine. Ideally, a novice avian practitioner would work directly with an experienced avian veterinarian. When this is not possible, a referral/phone consultation relationship with an experienced avian veterinarian will allow one to comfortably refer complicated cases, and to properly handle those cases that are within one's current skill level, while one's diagnostic and therapeutic abilities increase. Wild bird rehabilitation organizations are often in need of veterinary services. In exchange for these services, practitioners will gain valuable experience in handling and will build confidence in their surgical abilities without fearing the loss of a beloved pet bird. Ownership of birds of various species will make the practitioner comfortable with behavioral differences among species.

The goal of this text is to assist the veterinarian in becoming a competent avian practitioner. Knowledge of one's limitations regarding both equipment and experience is part of this qualification.

The American Animal Hospital Association (AAHA) 2003 study on standards and patient care states that failure to educate clients is the leading reason pets do not receive optimal care (this study is available on the AAHA web site, see Table 1.1)¹ A knowledgeable staff and appropriate educational support material is the underpinning of client compliance (Figs 1.1a-c).

MARKETING SERVICES

Once the decision has been made to incorporate avian medicine into the practice, attracting prospective clients is a priority. This can be accomplished through advertisements in various modalities, including the telephone directory, various Internet group listings, newspapers,

pet stores and in the "veterinary services" section of bird magazines. A guide to help locate additional advertising venues is available.⁴

The following questions can be used to define specific emphases within avian medicine. Some items may present areas for future expansion of your knowledge and the scope of your practice's client services.

What makes your practice distinctive?

Does your practice possess specialized equipment and procedures (eg, endoscopy, laser unit, microsurgery)? Does your veterinary or technical staff have specific training in the areas of avian medicine, surgery, nursing or behavior?

Are classes or consultations offered to clients for behavior disorders?

Does your practice carry recommended diets, bird-safe and appropriate toys, perches or caging?

Are house calls offered?

Is emergency service for avian patients provided?

Colleagues who do not treat birds can be a good source of referrals. Pet store owners and bird breeders may refer their customers if a good relationship is developed with your practice.

Bird marts, bird shows and bird fairs are very popular in the USA. Educating the public of the inherent dangers of these bird fairs should be a goal of avian veterinarians, responsible bird breeders and bird clubs. Currently, such events involve bird traders, neophyte hobbyists (the latter group often having the best of intentions) and a number of uneducated individuals, who often purchase birds on impulse. Birds at these fairs sometimes are poorly bred, incorrectly fed and/or improperly raised. Husbandry practices prior to the fair are unknown, and the co-mingling of species from various breeders that occurs at the fairs can be a major source of disease exposure and transmission. If a bird is purchased from a bird show or bird fair, it should be guarantined from other birds in its new household, although this seldom is accomplished. Sadly, the volumeoriented, discount-minded pet store often is a similar source of potentially diseased and compromised birds. Fortunately, awareness of these problems is increasing in both the USA and the EU. In the interim, encouraging clients to at least consider the methods of breeding, raising, feeding, testing and hygiene that are practiced by the seller prior to purchase will decrease the risk of acquiring a sick or debilitated bird. See Chapter 3, Concepts in Behavior for comments on proper husbandry and raising techniques. For guidelines on helping owners to choose a pet bird, see Chapter 2, The Companion Bird.

Despite all these problems, avian and exotic animal expositions are an acknowledged source of potential clients.

Fig 1.2 \mid Bird expositions are a common source of sick birds in the pet industry.

Renting a booth and showcasing your clinic will allow you to meet hundreds of bird enthusiasts. Although this is a high-visibility opportunity that may bring new clients, there are disadvantages. The most obvious problem is that the very presence of an avian veterinarian at these shows implicitly condones their existence. (Fig 1.2). Therefore, conflicts of interest may arise between sellers, buyers and veterinarians at such an event.

Dr. Jan Hooimeijer of The Netherlands has developed a unique offering for bird owners who desire to share their passion for their birds. He implements a strict client education program and regimented standards that must be met by the clients. These include recommendation of an organic formulated diet, disease testing and behavior classes. Log on to www.harrisonsbirdfoods.com for further information. Dr. Hooimeijer's clients are then invited to attend a "Bird Walk," a yearly celebration held in a local park, and the public and media are invited to attend. Some 400 clients and their family members attended in 2002, and the event was covered by national television (Figs 1.3a,b).

Another modality for attracting clients is to offer free educational classes after hours in the clinic, a local pet store, local university or other continuing education facility. (Fig 1.4) The classes can cover topics such as choosing a bird, bird behavior, nutrition and first aid. Flyers for the classes can be placed in pet stores, university bulletin boards, supermart bulletin boards, and advertisements can be placed in local newspapers. The classes can be also be promoted with flyers in the hospital, on the clinic's web site and in the clinic newsletter. This will attract current clients as well as prospective ones who are interested in becoming more knowledgeable about bird care.

Client referral is an excellent method to increase clientele, reflecting the satisfaction of an existing client and generating positive advance impressions in a new client. The extent of this "word of mouth" client referral will be

Fig 1.3a,b | Dr. Jan Hooimeijer has an annual "Bird Walk" to proudly show off his clients and their family members. More than mere pets, Jan molds his patients into a cohesive unit. Bicycle rides and family outings like this strengthen the clinic-client bond. Clinic support of bird clubs or bird-oriented groups concerned with parrot welfare provides opportunities for the clinic to impact the bird world in a very important way.

based to a great extent on client satisfaction. Client satisfaction starts with a clean, comfortable, bird safe, well-planned clinic with a friendly, knowledgeable staff and minimal waiting time. When technicians and doctors have ample time to spend discussing educational material and answering questions, this reflects concern and genuine interest in the patient, which pleases clients and impresses upon them that the staff and doctors are competent. Clients also are impressed with professional achievement awards, certifications achieved by the hospital (eg, AAHA) or staff with advanced training. They appreciate knowing about areas of special interest and the number of years that the staff and doctors have been involved in bird treatment.

Let clients know about your continuing education efforts, any papers you publish or news items written about your clinic. These items can be put on web sites, in newsletters or in waiting room binders for the client to see.

Fig 1.4 | Classes at public meeting places and sanctioned by clubs, schools and other public groups serve as the bedrock of educated clients. This gathering at Pine Jog Environmental Center in 1970 led to a university course on aviculture at Florida Atlantic University. From this small group came leaders of aviculture, founding secretary of Avian and Caged Bird Society of Ft. Lauderdale, FL (Ellen Tannerhill); a president of the American Federation of Aviculture (Tom Ireland); head curator of birds at Sea World, Orlando (Sherry Branch); Harvard Botanical collection director (George Staples); organizational president, AAV and HBD (Greg Harrison); president of ZEN, editor, Exotic DVM (Linda Harrison); owner, Palm Beach County, FL, oldest bird pet shop, Fins, Furs and Feathers (Charlie Holland); four other pet shop owners and a dozen avid aviculturists. One lady later became the wife of the head of veterinary services at Busch Gardens, Tampa, FL — she and her husband still breed birds some 20 years later.

Fig 1.5 | A client waiting room with a pleasant presentation of safe toys, educational materials and veterinarian-only dispensed bird foods makes a strong statement about the value of these items. Selling only items endorsed by the staff reduces confusion and improves client compliance.

Having photos of recommended pet birds at various locations throughout the clinic lets clients know of your special interests. A photo album containing photos either solicited from your clients, or taken at your hospital of the clients and their birds, is a very popular item in the waiting room.

FOOD, TOYS AND OTHER BIRD PRODUCT SALES

Clinic service and income can both be increased through the sales of recommended bird food, toys, books, perches, carriers and various other products. Toy selection should be based on bird-safe toys (Figs 1.5, 1.6a,b)

Fig 1.6a | Unsafe toys include clips like the one caught on this African grey's beak. For more on safe toys, see Chapter 6, Maximizing Information from the Physical Examination.

Fig 1.6b | Unsafe toys can trap a bird by the foot or leg. With its owners in the next room, this Amazon was totally silent as it chewed its leg free from being caught in a toy's rings.

Fig 1.7 | Just because a toy is made for a bird does not ensure it is safe. The Amazon in fig 1.6b mangled its foot with this set of rings (top). Similar metal circles are used on this key ring toy (bottom), which could easily trap a toe or foot.

Fig 1.8 | Staff at The Bird Hospital removes unsafe metal (galvanized clanging metal bells and clips) and replaces them with stainless steel chain and chain "quick" links. Avoid man-made fibers like nylon in toys, and instead use natural cotton, leather, sisal or hemp.

Fig 1.9 | This boarding facility offers an observation window from the reception area. Plants, up-to-date periodicals, and a clean, fresh presentation attract clients.

such as woven palm leaves, leather, wood and unbreakable plastic. Since many chains, mirrors and toy clips (Fig 1.7) are made of unsafe metals, clips should be switched to stainless steel C-clips (Fig 1.8). These can be bulk ordered and the cost can be incorporated into the price of the toy.

AFTER-HOURS EMERGENCY SERVICES

Service availability is another factor in client satisfaction. Weekend and late-night office hours are a convenience for clients who work during weekdays. An answering service allows clients to talk to a real person after hours when needed. Clinic brochures can be offered to give information on office hours, special services and directions to the clinic.

Offering a 24-hour emergency service is an advantage that clients value and appreciate. One author (GJH) employs a reasonable policy that requires clients to have physical examinations performed on their birds at least

once yearly to be eligible for after-hours emergency services. The receptionist informs callers, shoppers, food and toy buyers that a physical exam and current testing are required for eligibility for emergency service and boarding services (Fig 1.9). This maintains client commitment to routine care for their birds and reassurance that they have access to emergency services when needed.

Qualified veterinarians may give special training in avian emergency medicine to local emergency clinic personnel. Such training should emphasize stabilization of sick birds and include basic nursing care such as the administration of injections, selection of medications frequently administered in avian emergencies, gavage-feeding techniques and general supportive care. Avian veterinarians in several major cities provide training programs including procedure manuals for emergency clinicians in their area. This often allows the avian veterinarian to consult on emergencies via telephone, decreasing the demands of providing 24-hour emergency care.

Fig 1.10a | House call kit.

 $\begin{tabular}{ll} \textbf{Fig 1.10c} & | & Suture, simple surgical instruments, heparin, slides \\ for smears and injectable antibiotics. \\ \end{tabular}$

Fig 1.10b | Needles, blood collection tubes, styptic and materials for record keeping.

Fig 1.10d | Rotary drill, stethoscope, culturettes, syringes and medications round out the kit. Fresh, clean towels and species-specific equipment like nets are included as called for by the house call.

COLLEAGUE RELATIONSHIPS

Developing and maintaining a positive professional relationship with colleagues benefits everyone. Local veterinarians can be excellent sources of referral cases. Lectures given at local veterinary associations will increase referrals from these colleagues.

HOUSE CALLS

House calls are a convenience that clients appreciate. This is especially important for clients with numerous birds or birds that are too large (swans, geese) to transport. A house call kit (Figs 1.10a-d) can be easily made using a tool kit from a hardware store. Significant data regarding husbandry and potential disease can be obtained with a visit to the home or aviary. (Figs 1.11a-e) A video of the facility can be a useful alternative if a house call is not possible. See Chapter 6, Maximizing Information from the Physical Examination for an ideal psittacine aviculture setup. For an example of a mobile practice see Figs 1.12a-g. Be certain to check with your state regulatory authority regarding any additional

requirements or permits that may be necessary when house calls are added to your current practice.

Practice Equipment

The operating microscope is one of the most useful tools in avian practice (Fig 1.13). A variety of types are available, and some have automated pedal switches that allow hands-free adjustment of focus, magnification power and zoom-in view. Some operating microscopes have photographic capabilities so that pictures can be taken of the image seen through the microscope. The operating microscope greatly enhances visualization during surgery. It is useful for physical examinations of smaller birds such as canaries and finches.

Head loupes (Fig 1.14) are helpful for enhancing visualization, and are less expensive and more portable than operating microscopes. A magnifying loupe allowing a minimum of 4 to 8x magnification is needed for many avian surgeries. Various of types are available, with and

Fig 1.11a | House calls reveal a world one would not suspect unless seen: several tens of thousands of dollars of champion-bred show canaries packed into 70 cages, stacked in one large room of a physician's home. An outbreak of polyomavirus allowed a rare visit into this private aviculture world. Infectious disease will rapidly spread in this type of inadequate housing.

Fig 1.11b | The husbandry of an aviculture facility is best observed firsthand. Note the hardware cloth door. This type of wire is zinc coated and potentially toxic. The feeding of seeds and allowing debris to accumulate are not ideal practices.

Fig 1.11c | Turtle eggs incubated in the same room with parrots. Salmonella and other problems are invited by such measures.

Fig 1.11d | Housing mixed ages and species together can potentiate disease outbreaks that a house call can identify and prevent.

Fig 1.11e | Rodents leave a black streak from body oil on the wall over this perch in the cockatoo facility of a prominent US zoo. The heavy stain indicated a lack of effective pest control measures.

without light sources. Head loupes make the field of view appear closer, rather than actually magnifying what is seen. Endoscopy equipment is another essential in avian practice (Figs 1.15a-h). Currently (and since the inception of avian endoscopy) the most commonly used endoscope is a rigid 2.7-mm with operating sheath (see Chapter 24, Diagnostic Value of Endoscopy and Biopsy). Several types of biopsy forceps are available to use with the operating sheath. Most endoscopes can be equipped with cameras and video monitors, and photographs can be taken from the image seen through the endoscope. These images can be recorded to a disc or printed as a hard copy, which allows documentation of the endoscopic procedure. There also is a 1.2-mm semi-flexible endoscope^a that is especially useful for endoscopy of the trachea of small birds such as cockatiels and canaries. A flexible endoscope^b is available and comes equipped with grasping forceps useful for gastrointestinal endoscopy and foreign-body removal.

Microsurgical equipment also should be a part of avian practice. This is discussed in Chapter 35, Surgical Resolution of Soft Tissue Disorders.

AVIAN ANESTHESIA EQUIPMENT

In avian medicine a semi-open, non-rebreathing system is recommended. Supplemental heat capability is critical for success in extended avian surgeries. For further information, see Chapter 33, Updates in Anesthesia and Monitoring. A mobile field units for endoscopy (Figs 1.16g-f) and anesthesia (Figs 1.16g) can be made.

ULTRASOUND

Ultrasound can be a useful diagnostic modality, although its use in birds is limited by patient size, conformation and by the presence of air sacs. Ultrasound is particularly useful in differentiating abdominal swellings. Further information on avian ultrasonography can be found in Chapter 25, Advances in Diagnostic.

Fig 1.16a | Steps to custom power an endoscope for portability. The embedded magnification focus lens is removed from over the light of a Surgitel magnification scope.

Fig 1.16b | Close-up of removed lens (left) and the custom-made adapter (right) to allow this unit to power an endoscope.

Fig 1.16c | The modified light is ready to be attached to the endoscope.

Fig 1.16d | Light source snapped onto the endoscope.

Fig 1.16e | The final scope with battery pack for full mobile endoscopy. The author (GJH) uses it for tracheoscopy without anesthesia on canaries. This is a portable, lightweight field unit and it also produces more than enough light.

Fig 1.16f | Alternatively, an electrical plug can run the unit instead of battery power. The total unit price is several thousand dollars less than a traditional light source and flexible fiberoptic cable.

Fig 1.16g | A field anesthetic setup. A plastic drink bottle is filled with cotton wool and two straws or tubes are glued in place, one in the opening of the bottle neck and the other in a hole made near the neck. The neck tube is attached to a second bottle fashioned as a facemask induction chamber. The bird is placed in the induction mask and a towel seals around the neck. The anesthetist puffs (blows) on the second tube in the bottle with the cotton that has had 10 cc of isoflurane, halothane or ether added to the cotton. The anesthetic gas enters the induction mask. No more "blowing" is done until the level of anesthesia is so light that more gas is needed. Human exposure to volatile anesthetic gases must be considered when using an open system such as this without suction or exhaust. This semiclosed system avoids the waste of a mask with cotton and anesthesia in the mask itself. In a plain mask system it is difficult to control the anesthetic depth. With the anesthetic generator chamber one has more control, which in this case required covering the chamber with a stocking cap to keep the chamber temperature lower, as the sun produced heat that was causing too much anesthetic in the air-gas mixture, and birds were going down too fast and too deep.

Fig 1.17a | Metal toxicosis is seen commonly in avian practice. A "bag rad" technique is used as a preliminary scout film to make scout films fast, affordable and safe.

Fig 1.17b | The bird is placed in a bag sealed with tape and the bag is placed on the cassette; the exposure is made.

Fig 1.17c | Bird in bag on the cassette being exposed.

Fig 1.18a | Heart-liver-coelomic area view of a cockatiel, with no metal densities.

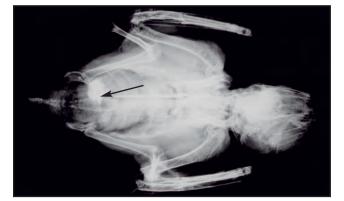

Fig 1.18b | "Metal" density (arrow) in ventriculus area in left caudal lateral aspect, liver swollen, increased shadowing of lungs and heart area.

RADIOLOGY

Radiology in avian medicine is discussed in Chapter 25, Advances in Diagnostic Imaging. In cases where radiology is used to identify metal-dense particles, anesthesia is not needed, since proper positioning is not required. Most birds can be safely placed in paper bags (Figs 1.17a-c) and placed directly on the cassette for radiography. This allows a scout film to be safely made and metal densities to be visualized (Figs 1.18a,b).

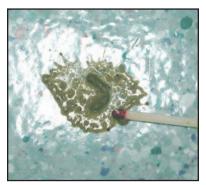

GRAM'S STAINING

Laboratory sampling is discussed elsewhere; however, Gram's staining will be mentioned here and in Chapter 4, Nutritional Considerations. In past decades, Gram's stains of feces and choanal swabs were used as a major method of testing newly imported birds. The paucity of knowledge at that time regarding the methods of safe venipuncture and subsequent interpretation of results made Gram's stains and cultures the only available diag-

Fig 1.19 | A simple Gram's staining rack that confines the stains to the sink area.

Figs 1.20a,b | Placing a wooden-stemmed match head into a bird's cloaca stimulates the production of a fresh sample. Feces are usually produced moments after placing the match in the cloaca.

Fig 1.21a | Small birds can be restrained as shown to make jugular venipuncture easier. It stretches the neck out in an ideal fashion for small to medium-sized birds. One pulls the right wing caudally to be held with the leg on the same side as the wing. At the same time the head is held. A second person draws the blood sample.

Fig 1.21b | Lovebird being restrained using clamps to hold a towel around the neck like a whiplash collar, immobilizing the bird.

Fig 1.21c | Pelican bill restraint.

Fig 1.21d | A restraint device for positioning a bird for radiography or surgery.

nostic tools. In retrospect, this use of Gram's staining was less than optimal, and the results of the Gram's stain often were misinterpreted or over-interpreted.

Currently, in these authors' practices, Gram's staining of fecal material is done routinely and prophylactically. These authors have found that a bird's intestinal bacterial balance is an excellent reflection of its general nutritional state and thus more of a determinate of wellness

than of illness.

The procedure can be very messy, and various racks (Fig 1.19) make this more manageable. Gram's stain solutions can be purchased in large-quantity containers, making the cost per test minimal. Ideally, the client is instructed to bring fresh, voided feces as part of the patient evaluation (see Chapter 4, Nutritional Considerations). If the client lives a long distance from

Fig 1.22 | a. Single-handed restraint to start a wing clip b-d. The foot and wing are restrained simultaneously. Wing trim in a light-bodied bird.

Fig 1.23c | In an Amazon trim, secondaries only (distal to elbow) are clipped on one wing.

the clinic, there is a recommended method for getting a fresh sample (Figs 1.20a,b).

RESTRAINT

The restraint of birds such as raptors and other birds of prey is discussed in the special species chapters. The towel restraint is discussed in Chapter 6, Maximizing Information from the Physical Examination. For grooming, the towel makes single-person restraint and procedural accomplishment possible. Old towels can be purchased inexpensively at thrift or secondhand stores. Washcloths work well for smaller birds such as budgerigars or parrotlets, hand towels are ideal for cockatiels and lovebirds, and larger birds such as Amazons and macaws need to be wrapped in full-sized bath towels.

Small birds can be held for jugular bleeding as shown (Fig 1.21a). Towel clamps can be used to secure the towel once the bird is wrapped (Fig 1.21b). Waterfowl, wading birds and water birds in general need the beak controlled (Fig 1.21c) while raptors need foot restraint that will prevent taloning or "footing" of either the handler or of the bird itself. A plastic restraining board^c (Fig 1.21d) is ideal for restraining birds for radiography and certain other procedures under anesthesia.

AVIAN GROOMING

Grooming birds consists of wing trimming, nail cutting, beak trimming and bathing. Wing trimming for large birds involves taking off a variable number of the primaries (see Chapter 6, Maximizing Information from the

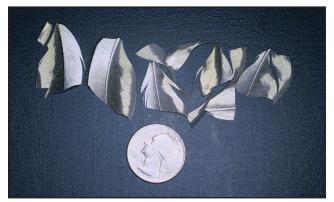

Fig 1.24 | Number of feathers removed from a cockatiel to stop flight. The bird was flying after an incorrect wing trim.

Fig 1.25b | After removing scab.

Fig 1.25d | This photo shows the number of feathers pulled from the bird in Fig 1.25c. This is a form of forced (non-drug) molt. New feathers will grow in over the following few weeks. The bird must be kept on the floor or in a perch-less cage during regrowth to avoid falling.

Fig 1.25a | Sternal ulcer from falling due to over-clipped wings.

Fig 1.25c | An African grey, a heavy-bodied bird, that was falling and creating a sternal ulcer as seen in Fig 1.25a. The bird is having trimmed feathers pulled under anesthesia to speed feather regrowth. Use a firm grip with a needle holder, pull gently and steadily to avoid ripping the follicle and surrounding membranes.

Fig 1.25e | Several weeks after the wing feathers have regrown, the bird regained stability and then flight. At this time, the wing should be properly trimmed. If additional sternal trauma can be avoided for several weeks, the ulcer will heal by second intention. Proper diet speeds up feather regrowth and healing.

Physical Examination and Figs 1.22a-d and 1.23a-c). The primaries are cut as closely to their insertion as possible. Currently, the most popular method of wing trimming is to remove a variable (4-7) number of distal primary feathers from both wings. In the authors' practice, largebodied birds have primary feathers cut from their right wing only, from the elbow to the tip of the wing. Small

birds can usually be groomed by clipping both the primaries and some of the secondaries. Since there are many modifications to wing trims, it is NOT safe for birds to be carried free outdoors after ANY wing-trimming procedure. Fig 1.24 shows the limited mass of feathers needed to achieve flight in a cockatiel that was inadequately trimmed.

Fig 1.26a | Beak and nail trimming. The stone on this electric hand-held rotary tool* has been "loaded" with plastic or paint by grinding such a surface in such a manner as to "load" the stone, creating a smooth surface. This smooth surface generates heat for cautery if a beak or nail starts to bleed during trimming.

Fig 1.26b | Positioning the upper beak (maxilla) inside the lower beak (mandible) to accomplish a controlled trim and avoid tongue damage. Note the bracing of fingers one against another to allow fine controlled motions.

Fig 1.27 | Nail trim in a small bird, single-person hold. Brace fingers against one another for maximum control.

Fig 1.28a | Grinding a baby macaw's nails and accustoming it to the rotary tool. Older birds unaccustomed to this procedure should always be restrained to avoid biting or grabbing the drill or causing injury to the bird.

Fig 1.28b | Using the towel restraint (see Fig 1.23), the foot and toes can be controlled. Note the leveraging of the fingers one against another to provide accurate control.

Fig 1.28c | Changing angles and finger positioning to allow complete honing of each nail.

Conversely, excessive feather removal in heavy-bodied birds can result in sternal ulcers from falling onto hard surfaces (Fig 1.25a-e). African greys (*Psittacus erithacus*) and some macaws, cockatoos and Amazons develop necrotic ulcers of the skin over the distal wing that heal when the cut feather stubs are pulled under anesthesia. Personality changes from the sudden instability created by a wing trim can occur, especially in sensitive species such as African greys. It takes weeks for new feathers to emerge. In the authors' experiences, sternal ulcers usually heal successfully by avoiding further trauma (keeping the bird from falling repeatedly) and allowing feather regrowth. No medical or surgical (sternal keel reduction) treatment is usually needed if recurrence of the trauma can be prevented.

Beak trimming is not necessary in birds unless the beak

is overgrown due to underlying health problems or malocclusion. Some clients will request the beak be dulled to mitigate mutilation or the pain to themselves or others from being bitten.

Cement (concrete) perches are useful for providing a rough surface on which the bird can clean its beak. Even birds that will not stand on a cement perch will often utilize one for cleaning food debris and excess keratin off the beak. These perches can be hung vertically in the cage to provide the bird with better beak access. Some of the available commercial cement perches are too rough and can cause plantar surface irritation, especially if the cement perch is located where the bird elects to perch for prolonged periods of time. Other brands are too smooth and are therefore not effective in providing an abrasive surface for the nails or beak (T. Lightfoot, personal communication, 2003). A hand-held rotary

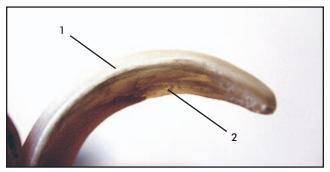

Fig 1.29 | Close-up view of a nail. Simply cutting the parrot's nail tip does not address the two sharp edges of the nail that are normally present (1,2). Controlled honing with a grinding or filing device leaves a smooth-surfaced nail and provides weeks, longer satisfaction for the client. Explaining this to the client and keeping towels and rotary tools sterile justifies the additional charges needed for a veterinary facility to provide grooming.

Fig 1.30a | Bathing of birds is a part of grooming. Thorough rinsing, towel drying and, in some birds, blow-drying may be used.

Fig 1.30b | Some "advisors" suggest blow-drying can be a cause of dry skin and that birds do not like blow-dryers. "Papagei," a pampered Moluccan cockatoo, thoroughly enjoys his bimonthly bath and blow-dry. He moves on his own to get each spot dry. He does not have a dry skin problem.

Fig 1.30c| The use of a feather cleansing solution provides a good vehicle for topical medications (ie, heparin, F10).

toole is ideal for trimming beaks and nails because it files the tissue back in a smooth, controlled manner. Furthermore, the heat generated by friction from the filing tip facilitates cauterization if bleeding occurs. A conicalshaped rasping tip (Fig 1.26a) works best for avian grooming. Caution must be used when honing the sides of the rhinotheca, as the final protective/germinal layer is very thin and can easily be ground through or burned, creating a long-standing deficit. To facilitate shortening of mandibular rhamphothecal length, the maxillary rhamphotheca can be inserted inside the mandibular rhamphotheca (Fig 1.26b). This positioning not only makes the mandibular rhamphotheca more accessible, but also helps prevent the patient's tongue from making contact with the rotary bit.

Restraint for nail trimming is demonstrated (Figs 1.27, 1.28a-c). As the rotary tool is held, fingers should be positioned to allow maximum dexterity. Birds have sharp ridges on the sides of their nails, and this is why they remain sharp when only the tip of the nail is removed (Fig 1.29). The rotary tool is ideal for smoothing ridges so nails do not feel sharp. Again, as with wing trims, clients should be forewarned that the bird will be less able to maintain its balance after a nail trim and will be more likely to fall from its cage or the owner's shoulder when the nails are dull.

Giving birds a bath with soap and water is not a routine part of the grooming process as with cats and dogs. However, some birds really enjoy the process, as do the owners. The type of soap that is used for fine washable garments has been noted as safe and effective for birdbaths for the past three decades. It is recommended that one drop of soap per 250 cc water be used for routine bathing. Up to 3 cc soap in 250 cc water may be used to clean more heavily soiled feathers. The bird should be subsequently rinsed in warm water, towel dried, then blowdried with an electric dryer (assuming the bird accepts this procedure) (Figs 1.30a-c), taking care not to burn the skin.

Fig 1.31a | An aluminum leg band.

Fig 1.31b | If the band is too large it can be easily slipped up over the ankle and removed intact.

Fig 1.31c | Bring digit 1 of the banded leg up along the metatarsus and slip the band down over that digit.

Fig 1.31d | Continue to slip the band off.

Fig 1.31e | The band is off. Reversing the process allows the band to be put back on for travel needs.

Fig 1.32a | Metal cutting pliers can cut only aluminum bands. They will only slightly dent the stainless steel band shown here.

Fig 1.32b | To custom-make a very small bird band remover an Olsen-Hager needle holder on the left can have the needle holder plates ground off as shown in Fig 1.32c.

Fig 1.32c | The flat grind wheel on a handheld rotary tool° can be used to remove the needle holder's tips and make the cuts shown in Fig 1.32d. This makes an excellent band remover for the fine plastic bands and some aluminum bands used for birds like canaries.

Fig 1.32d | Close-up of the cuts made to create a band remover from a needle holder.

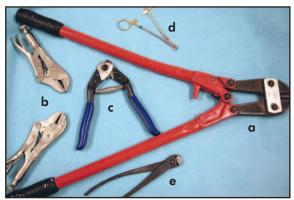

Fig 1.32e | A collection of tools used to remove various leg bands: Bolt cutter (a), vise or locking pliers (b), metal snips (c), modified needle holder (d), Kras cutter^f (e).

Fig 1.32f | Side cutters and needlenose pliers are examples of tools used to cut bands and hold metal for bending or cutting.

Fig 1.32g | Close-up of band-cutter heads. Metal snip (a), modified needle holder (b), Kras cutter^f (c).

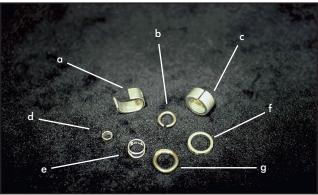

Fig 1.33 | Three split bands (a,b,c): (b) A stainless steel band that requires a bolt cutter or a two-vise-grip twist to be removed. (d,e,f) Aluminum bands: (d) and (e) can best be cut with modified needle holders; (f) requires one of the two tools shown in Fig 1.32e. (g) A solid stainless steel ring that requires bolt cutters once or twice and then vise grips.

Fig 1.34a | A leg constricted by a band due to accumulation of exfoliated skin under the band.

Fig 1.34b | Malnutrition creates a proliferation of the scales that can accumulate under a band. Over time, a depression in the leg's structure is formed by the proliferating skin mounding between the band and the leg. Pressure from this accumulation under the band causes constriction of the leg vessels. The foot can be lost due to necrosis. The custom-made needle holder band remover usually works best on this problem if the band is aluminum.

Fig 1.34c | A metal snip also can be used to cut aluminum bands constricting the leg.

Fig 1.34d | Pressure necrosis caused by tissue proliferation makes a deep groove that severely compromises circulation.

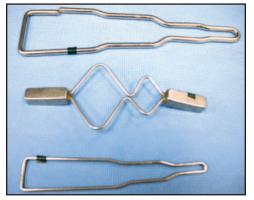

Fig 1.35 | A variety of mouth specula.

Fig 1.36 | A mouth speculum cut to reduce beak cracking.

Fig 1.37 | Sections of plastic pipe used to make a speculum with a hole through which a gavage device can be passed.

Fig 1.38 | Various metal gavage tubes.

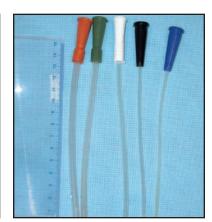

Fig 1.39 | Silicone feeding tubes^h.

BAND-REMOVAL INSTRUMENTS

Oversized bands can be slipped off the foot. The band is slipped proximally over the tibiotarsal-tarsometatarsal joint (hock) as high as possible (Fig 1.31a-e). Digit 1 is retracted along the joint as shown and the nail is placed under the band. If needed, a lubricant can be applied. With light pressure the band slips off. It can be replaced later if need be. Band cutters¹ work well for removing most small, closed bands. (Figs 1.32a-g) Bands that are too small (Fig 1.33) or build up layers of keratin under them from nutritional disorders can cause constriction (Figs 1.34a-d). The larger steel bands are too strong to be cut with most band cutters and must be twisted off using vise grips or split with heavy metal (bolt) cutters (large red-handled device in Fig 1.32e).

OTHER EQUIPMENT

Specula

Stainless steel specula have the advantages of being indestructible and easy to sterilize (Fig 1.35). However, if the bird bites down aggressively on the speculum, damage to the mandibular beak can occur. Cutting one side of the speculum so that it is slightly moveable can mini-

mize this potential problem (Fig 1.36). Specula are also made from tubular plastic material (Fig 1.37). Plastic specula are commercially available and are found useful by some practitioners to obtain pharyngeal swabs for PCR tests or culture. Two pieces of gauze also can be used to hold the beak open. For most procedures, a speculum is not necessary.

Feeding Tubes

Because they are indestructible and easily disinfected, stainless steel feeding tubes^g (Fig 1.38) work best for most pet birds. Disposable silicone tubes^h (Fig 1.39) work well for tube feeding neonates, waterfowl or other birds that cannot bite the tube. Red rubber catheters^g are ideal for long-necked birds such as seabirds. See Chapter 14, Evaluating and Treating the Gastrointestinal System for photos of damage avoidance and proper tube placement.

Microchipping Equipment

Microchips are small electronic devices that can be injected into the body. The left pectoral muscle is the accepted placement of microchips in psittacines. These devices contain a code that, when scanned with a reader, will provide identification of the bird. One disadvantage of

Fig 1.40 | A Moluccan cockatoo on the perch on a scale.

Fig 1.41 | Disposable paper bags make easy restraint devices to weigh small birds and require no cleaning.

Fig 1.42 | A plastic tube perch in a cage.

microchips is that there is no industry standard, and one model of microchip reader cannot identify all microchips.⁶ The USA's FDA and USDA have approved a combination AVID code and Fecava code 125-kHz chip reader.^{1,11} In Canada, Western Europe and Australia, the chips operate at 134.2 kHz. This ISO chip can be read with a global scanner, but not by the USA 125-kHz scanner, which only reads the corresponding chip.

Gram Scale

Pet birds need to be weighed in grams. Modern digital scales allow placing the bird on a perch (Figs 1.40). The tare function on these scales will allow automatic deduction of the weight of a box, bag or towel from the digital readout. These digital scales can be fitted with an AC adapter to avoid constant battery replacement. Most pet birds will sit on a perch to be weighed. For those that do not, various bags (Fig 1.41) work and they are replaceable without cleaning.

Examination and Clinic Cage Perches

Acrylic perches[†] (Fig 1.40) are ideal clinical perches for the exam room because they are relatively inexpensive and can be easily disinfected. Plastic tube perches are inexpensive, easy to clean and the material with which to construct these can be purchased at any local hardware store in multiple diameters. This plastic piping can be cut to any length to be custom fit to cages (Fig 1.42). Wrapping these plastic (PVC) perches in removable self-adhering bandage material (ie, VetWrap) offers the bird better traction while perching, and hygiene can be maintained by changing the wrap between patients.

PATIENT PRESENTATION

Birds should be presented to the clinic in travel cages

(Figs 1.43, 1.44; see Fig 1.51b), not on the owner's shoulders (Fig 1.45). This is to prevent injury to bird or owner. Restraint for assisting doctors, grooming or administration of treatments is most effectively achieved as previously discussed using a towel.

Avian Practice Staff Members

All clinic staff should sign clinic confidentiality agreements; professional staff should include this agreement as part of their employment contract. Contracts should have buy-outs and exit strategies well outlined and should be renewed to keep them effective. Without these procedures chaos is invited.

The delineation of duties within the course of an avian appointment will vary between practices. The relative experience of staff, technicians and doctors, as well as the ratio of these and the current level of activity, makes cross training and flexibility advantageous, as in any veterinary practice. In order to give concrete examples of how the various steps involved in a patient visit can proceed, the authors have assigned specific responsibilities to each staff member in the following examples.

RECEPTIONIST

The demands of avian medicine are different from the demands of small animal practice; therefore, staff members should be appropriately trained. The receptionist is the client's first contact with your hospital and a major representative of the clinic. The receptionist should make clients feel welcome and comfortable and should be educated enough to answer questions concerning general

Fig 1.43 | Bird in a carrier made of hardware cloth, which is a potential source of zinc or lead. Lead will will cause a wet test strip ¹¹ to turn red.

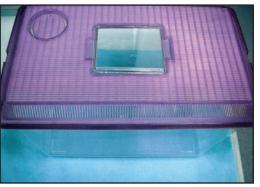

Fig 1.44 | A plastic storage box used to transport birds and other small pets.

Fig 1.45 | A hyacinth macaw on its owner's shoulders. An improper presentation mode for a clinical visit.

bird care. A competent receptionist should be able to successfully complete paperwork and expedite clients as they move in and out of the waiting room. Other responsibilities for the receptionist may include debt collection, retail ordering of food and toys, organizing reminder cards, initiating client callbacks and other communication to be sent out to clients. A skilled receptionist can turn the telephone shopper into an appointment.

VETERINARY ASSISTANTS

Finding certified technicians with avian experience often is very difficult. Therefore, one is often forced to train assistants to support the veterinarian in certain duties. While seldom competent in all areas taught to veterinary technicians, enthusiastic assistants can provide a great deal of support. Assistants often can be taught many of the technical duties: client questioning, performing fecal Gram's stains, administering drugs, and assisting in radiology and surgery. Assistants can perform procedures but seldom understand all the ramifications or anatomical, physiological, pathological and pharmacological reasons for their actions. Depending on the size of the hospital and the presence and extent of avian boarding, the veterinary assistant and kennel assistant may have overlapping duties (see the following section on Kennel Assistants).

Technicians, on the other hand, know why they are doing what they are doing. They often can support the veterinarian by offering suggestions based on practical understanding, demonstrating the huge difference between assistants and technicians.

VETERINARY TECHNICIANS

Veterinary technicians are certified as to their special training. They often need further experience and guidance to adapt to birds. Training opportunities are available at special seminars or conferences, such as the Association of Avian Veterinarians' annual conference and the International Conference on Exotics (ICE). There also are programs available through technical colleges throughout the USA. A complete list of veterinary technology programs in the USA is available in the American Veterinary Medical Association Directory and Resource Manual (Table 1.1). Although there currently are no technical programs that specialize in avian medicine, most programs do cover exotic animal care. Following are descriptions of responsibilities that technicians can be trained to perform.

Client Communication

There is a recognized lack of accurate information available to pet bird owners. This can be overcome by training technicians to give short talks during appointments on dietary requirements, husbandry and home care. See Chapter 6, Maximizing Information from the Physical Examination for a form that covers these topics. Technicians also can become involved with writing and distributing educational handouts and presenting classes.

Initial Examination

After reception, the technicians or assistants project the clinic's second image to the client. They take the bird into the exam room, review the case history and records, and verify that the paperwork is correct including name, phone number, bird's name, age, sex, species and color. They should present the clinic philosophy of wellness and education, offer take-home educational material and start the medical record. (See Chapter 6, Maximizing Information from the Physical Examination for a form that can be completed by the support staff.) Procedures are more readily understood and accepted by the client if visual educational material is presented. Diet, preventive practices, and the physical exam are discussed and performed. An information video on the value of proper

Fig 1.46 | A steam cleaner^k makes dried matter easier to remove.

diet can be shown. A sample of fresh feces is Gram's stained in the laboratory. The veterinarian can then come in to evaluate the records, complete the physical examination, record the clinical signs, and form and record a list of differential diagnoses. These are then discussed and the diagnostic tests necessary are explained to the owner. The technician records these and prints out an estimate, including the diagnostic and treatment protocols. This is explained to the client by the technician, then approved by the client. The owner can then sign treatment permission and price quotation forms.

Under veterinary supervision, technicians draw blood, perform laboratory tests and collect, prepare and properly submit laboratory samples. Technicians also review cases daily with the veterinarian.

Technicians should monitor boarding and hospitalized birds on a daily basis noting and recording appetite, fecal production, weight and behavior. If any abnormalities are noted, these should be discussed with the doctor. In addition, technicians should become competent at performing routine treatments, preparing medications to be dispensed, administering injections, gavage-feeding, administrating oral and topical medications, and performing radiography, cytology and blood collection. Technicians are usually familiar with medical terminology so they can take notes for doctors during exams, surgery and necropsies. Taking radiographs, ordering medical and surgical supplies, contacting owners for follow-ups on laboratory reports and preparing instructions for patients being released are tasks a technician often masters. A competent technical staff with such skills is irreplaceable. Technicians also assist in surgery, including preparing the operating room for surgery, monitoring anesthesia and patient recovery, and cleaning and sterilizing instruments after

surgery. A new small steam generator* is available for equipment cleaning and is efficient, effective and very affordable. The steam sterilizes as it loosens debris and reduces the need for chemicals (Fig 1.46).

Hospital inventory

Technicians should develop a rapport with several medical supply company representatives, increasing the chances of finding the best prices on drugs and hospital supplies. In addition, a pharmacy inventory should be kept so that stock can be kept up to date and reordered when needed. Shelves should be checked on a regular basis to remove expired food and drugs.

KENNEL OR HOSPITAL ASSISTANTS

Kennel or hospital assistants are responsible for weighing birds daily, and for clinic sanitation including cleaning cages and rooms. Assistants should be comfortable around birds because cleaning often necessitates handling birds without getting bitten, injuring the bird or permitting the birds to escape. Assistants should be astute enough to observe any abnormalities in feces, appetite or weight changes, so that technicians and doctors can be notified. These employees must be able to recognize proper placement of perches, food and water bowls within the cage to make certain the bird is accessing these. For example, a nervous bird may sit on a high perch in an unfamiliar animal hospital environment and not venture down to the level where the food and water are placed. Assistants also may be responsible for making sure that food and toy supplies are stocked on shelves and ensuring that any such items offered to hospital and boarding birds are safe and appropriate. Individual items such as cups, toys and carriers should be marked with the owner's name so that they are returned when the patient leaves the hospital.

AVIAN BEHAVIORIST

Biting, screaming and feather picking are frequently encountered problems with pet birds. Owners often do not know how to react correctly without reinforcing the problem. It is ideal to have an in-house bird behaviorist to work with clients to overcome these types of problems. Behaviorists also can train birds (and their owners) to overcome such bad habits as refusal to perch and insisting on staying on the owner's shoulders. Training for behavioral work can be obtained by attending conferences and seminars and by consulting with behavioral experts. For further information see Chapter 3, Concepts in Behavior.

Hospital Facilities

BOARDING

Fig 1.9 shows boarding birds that can be seen from the reception area. The presence of a "clinic bird" in a mixed small animal practice often serves to announce the practice's interest in birds.

Boarding birds should be housed in an area located away from noise and excitement. This is easier to do in an exclusively avian practice versus a small animal practice, where birds must have a special area away from dogs, cats or other exotic animals. Stainless steel or fiberglass cages, such as those used for dogs and cats, work well for housing birds because they are indestructible and easy to clean. Some stainless steel cages can be padlocked (Fig 1.47), which is useful to safeguard "escape artists" and help ensure the security of very expensive birds. Plastic pipe for perches can be cut to any size to fit in cages. White butcher paper (Fig 1.48) is non-staining and can be used for the cage lining. The white paper allows quick visualization of fecal and urate color and consistency, and this helps monitor the bird's health. For smaller birds, cages can have the bottoms removed and be placed directly on the butcher paper, thus facilitating cleanup.

Central vacuum systems (Fig 1.49) make cleaning easier.

Central vacuum access in the surgical preparation area is also an advantage, allowing feathers to be immediately vacuumed as they are plucked.

Preliminary Testing for Boarding Birds

The policies that are implemented for testing prior to boarding should be tailored to the individual bird and its particular risk factors. For example, juvenile birds, birds that are exposed to other birds at bird shows and those that accompany their owners to pet stores, should be tested more frequently. It is good policy to require every boarding bird to have a physical examination and a minimum laboratory base-line, including a Gram's stain, within 6 months of boarding. It may be prudent to require a psittacosis PCR test at the same interval. This not only reduces the potential that sick birds will be housed with healthy birds, but also provides client lovalty for the clinic. Birds that have not been tested or have test results pending must stay in an isolation room until the test results have been received. An extra daily fee is justified for housing in isolation.

TOYS FOR BIRDS

Many clients will purchase toys for their boarding and recovering birds. This is good for the bird and also generates income for the clinic. Alternatively, the clinic can provide inexpensive toys such as native nontoxic woods or palm leaf pieces (Fig 1.50).

Fig 1.51a | A cockatiel in plexiglas container.

Fig 1.51b | Acrylics are lighter and more scratch resistant than plexiglas.

Fig 1.51c | Hospital intensive care unit with toys.

Fig 1.52 | A plastic tub, its top replaced with wire and with a heating pad underneath, makes a practical homecare unit.

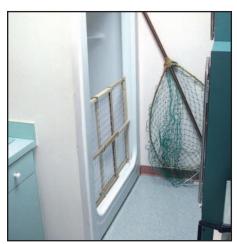

Fig 1.53 | A shower stall is made into a cage by placing a flexible panel used to block doors for toddlers. This makes a practical, easily cleaned unit for water birds that need frequent cleaning with large volumes of water.

HOSPITALIZATION

The hospitalization room should be a quiet environment, separated from the boarding and isolation areas. Birds requiring supplemental heat should be housed in incubator-type enclosures. Many of these are equipped with a heat and humidity source. Most sick birds should be kept at a temperature of 26.7 to 29.4° C (80-85° F) and humidity of 70% (Fig 1.51a-c). A plastic container can be used as a brooder by cutting a section out of the

top and replacing it with wire (Fig 1.52). It is convenient to have hospital supplies, such as frequently used medications, syringes, needles and electrolyte solutions, located in the hospitalization room. Supplemental oxygen should be located in the hospitalization room for use with patients requiring oxygen therapy. Commercial brooder-incubators^p are available that allow control of humidity and temperature. The authors have found it easier to keep sick and recovering birds warm if air conditioning vents are not installed in hospital rooms; this also reduces air from these rooms circulating into wellbird areas. A simple electric space heater can be used to increase the temperature of bird rooms needing warmer temperatures. Heating pads under cages for heat and other forms of dry heat can cause dehydration. Humidity should be added as needed.

ISOLATION

An isolation area is necessary for housing untested birds or birds with unknown illnesses away from other birds in the clinic. Ideally, the isolation room should have a ventilation system that is separate from the main clinic ventilation system. Staff should be instructed to strictly adhere to precautionary measures associated with isolated birds. These include treating isolated birds last and having scrubs, gowns, gloves, shoe coverings and cold sterilization dishes that are to be used only for isolated birds. Staff also should be instructed on proper room disinfection procedures.

The authors' clinic uses a chemical autoclave that employs a form of alcohol rather than water for vapor. This machine is kept in the isolation room and birds are moved to a bathroom when autoclaving; thus, the fumes help keep this room sterile. Other than the bathrooms, this is the only room with an exhaust fan in the clinic. The clinic's isolation area contains a shower to house large waterfowl such as pelicans and swans (Fig 1.53). This area can be hosed down as needed to help contain odor and mess.

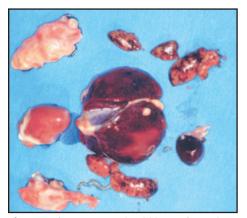

Fig 1.54 | Necropsies should be performed as often as possible in avian medicine to add to both the individual veterinarian's and the avian veterinary community's collective knowledge. A wide selection of tissues must be collected for histopathologic confirmation.

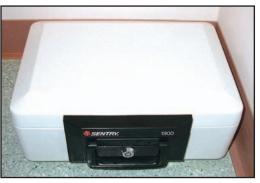

Fig 1.55 | A locked safe is used to store controlled drug and may be bolted to the floor.

In larger hospitals and those that also offer hospitalization and/or boarding for dog and cat patients, physical distance can serve as additional separation between multiple sick birds that need to be isolated. Fortunately, few contagious diseases of birds are commonly contagious to pet dogs and cats. Attention must then be paid to appropriate temperature, humidity, and lack of stressful stimuli when traditional companion pets are present with clinically ill avian patients.

CLIENT RELATIONS

Once a clientele has been established in the practice, it is important to make sure they return on a regular basis for continued care of their birds. Appointment reminders for semi-annual exams and laboratory testing, including Gram's stains and other recommended tests, should be sent out every 6 months. Client information folders¹ (see Fig 1.1b) can be given to clients so they have a record of body weights, health history and identifying characteristics of their bird. These are updated at each visit. Designing a client library that includes an avian veterinary medical text is also a good idea (see Fig 1.1b), although avian textbooks contain medical terminology that clients might have difficulty understanding.

Education and communication are important aspects of maintaining good client relations. Handouts with current information on pet bird health and disease are useful in clarifying information that was covered during the office visit. Topics that might be addressed include metal toxicosis in birds, importance of nutrition, safe diet conversion and zoonotic diseases of concern. Behavioral issues become more prevalent with increased length of ownership and are becoming more pervasive in our current pet bird population. Based on the bird's species,

age, temperament and relationship with its owners, each visit may be accompanied by the discussion of a specific behavioral concern. In addition, there are educational newsletters^m available for client distribution. Development of a clinic newsletter can be a positive addition to client education, retention and recruitment. This can cover new innovations in bird health as well as inform clients about new developments within the practice. Newsletters can be placed on the clinic web site. Educational brochures can be ordered^m to place in the reception area. These contain information regarding various pet bird species, first aid, signs of illness, specific diseases, nutrition and hand-feeding^a. Bird species identification books tend to be popular with clients. Having both normal and abnormal feathers available will demonstrate to clients the difference (see Figs 6.57k,l) between healthy and unhealthy conditions of their bird's feathering.

Educational material is available through companies that manufacture pet bird products such as food, cages and toys. Furthermore, most of the companies have web sites, and clients can communicate directly with company representatives via e-mail. With the advent of computer technology, web sites have become powerful tools for providing information to people all over the world. Setting up a clinic web site enables thousands of people to see pictures of clinic facilities and staff and to communicate questions directly via e-mail. A hospital web site with recommended links can also direct clients and potential clients to reliable sources of information on the Internet, providing a counterpoint to misleading and inaccurate information that can be encountered elsewhere on the web. As a convenience, appointments can be made via e-mail as well. E-mails can be sent to clients for follow-up office visits, and appointment reminders

also can be sent via e-mail. A clinic web site can provide an opportunity for clients to download the clinic newsletter, calendar of events or other educational information about pet bird health.

Another aspect of client satisfaction is conveying the message that the staff and veterinarians take a personal interest in the client. This can be accomplished by sending thank you notes for referrals and to thank new clients for their business. Clients also are very appreciative of expressions of sympathy such as cards, flowers or donations in their bird's honor when they have lost a beloved pet.

Record Keeping

COMPUTER SOFTWARE

Increased computer technology has brought many advances to veterinary medicine. One of the most important has been the increased efficiency and accuracy of record keeping through computer software developed for veterinary practices. Although there is no computer program currently available specifically for avian practice, it is possible to adapt small animal programs for use in avian practice. Estimates for future hospital services can be written and stored in the computer program. When an estimate is needed, the information can be easily accessed and modified, and presented quickly and accurately. Photographs and radiographs can be loaded into the patient's record. This is an advantage when records must be transferred or a patient is being referred, because the information can be electronically transmitted to another clinic, saving time and eliminating lost records. Computer programs are able to keep track of each client's visit and generate timely reminder cards. Computer programs store billing history and highlight bills that are overdue, making billing more consistent. Computer software also prints and records drug labels, which precludes mistakes due to illegible handwriting on labels, and allows directions for previous therapeutics prescribed to be retrieved. In addition, software allows auditing, individual access and monitoring for security measures.

DIGITAL CAMERAS

Another advance in record keeping is the development of digital cameras. Digital images allow information to be shared quickly among veterinarians via the Internet. With digital cameras, it is possible to capture images of the patient and any related conditions or procedures. Radiographs can be digitally recorded and the file sent to another practitioner without concern for the physical possession of the radiographs and associated legal

implications.

Additionally, the use of digital cameras for documenting necropsy findings can be invaluable. The complete necropsy shown in Fig 1.54 involves opening the skull and demonstrates the value of the camera while illustrating a critical portion of the necropsy that is often omitted by many practitioners.

For the highest quality pictures, digital cameras should have a built-in macro capability (to enable good close-ups) and should be capable of image densities of two megapixels or greater.³

There are special adapters that allow cameras to be mounted on microscopes to capture microscopic images, while the addition of macro lenses and built-in macro functions of some digital cameras will create exceptional images when placed directly onto one of the eyepieces of a microscope.

PAPERWORK

Although increasing numbers of veterinary hospitals have become virtually paperless, there are still several situations that are best addressed by signature authority. Authorization forms document the client's understanding of and consent to having a particular service or services performed and the terms of that service. Authorization forms are commonly used in avian practice, as are forms that limit liability.

SECURE ITEMS

Keeping cash, controlled drugs and vital records in a fireproof safe is important for security. Fireproof containers have a lining that generates moisture upon heating, making combustion less likely (Fig 1.55). These containers are guaranteed for only 5 years, as this function deteriorates over time.

CONTROLLED DRUGS

Controlled drugs, radiology monitoring, medical waste and OSHA training are areas covered by federal and state laws in the USA. Such subjects need to be reviewed with your national, state and local authorities.

General Information Avian Practitioners Should Have Available

TRAVEL FORMS

On many occasions, people wish to take their pet birds

with them while traveling. In some situations, it is necessary to have travel forms that permit the bird to accompany the owner.

Travel by car within the USA requires Interstate Health Certificates.

When traveling by airplane within the USA: Form SA-B (Official Certificate of Veterinary Inspection for Interstate Movement of Dogs, Cats, and Other Nonlivestock Species) must be filled out by an accredited veterinarian. APHIS form 7001 (US Interstate and International Certificate of Health Examination for Small Animals) also may be used for this purpose. Travel by airplane outside the United States: An accredited veterinarian must fill out APHIS form 7001. The bird owner must then mail or hand-carry this completed form to the designated USDA-APHIS office, along with a processing fee. The form will then be approved by a USDA veterinarian and sent back to the owner to accompany the bird during travel. Because of the time needed to process this form, owners should be advised that planning ahead is imperative in order to receive the completed paperwork in time for travel. Additionally, the country to which the bird is being exported may have its own forms that must be completed prior to exportation, and may have differing requirements regarding testing, vaccination and identification. The owner should check with that country's embassy in the USA prior to making travel plans. Travel with poultry or hatching eggs for export: There is a special form for poultry, VS form 17-6. Unless the birds are hatching eggs and newly hatched poultry, the veterinarian must go to the premise to inspect the birds in order to validate the travel form.

PSITTACOSIS INFORMATION

The Committee of the National Association of State Public Health Veterinarians has compiled a compendium of psittacosis control. The compendium discusses psittacosis infection among humans and birds, transmission, clinical signs and symptoms, case definitions, diagnosis, treatment, and recommendations and requirements. Copies of the compendium can be accessed at the Center for Disease Control web site (www.cdc.gov/ncidod) and at the web site for the American Veterinary Medical Association (www.avma.org).

IMPORT-EXPORT OF PET BIRDS

Most parrots are classified as endangered species, which require a special Conference on Endangered Species (CITES) permit to be imported or exported to or from the USA. See Table 1.1 and the discussion on Regulations in Chapter 2, The Companion Bird.

The

Companion Bird

ANGELA M. LENNOX, DVM, Dipl ABVP-Avian and GREG J. HARRISON, DVM, Dipl ABVP-Avian, Dipl ECAMS

More veterinarians than ever are willing to treat companion birds. The quality of avian medicine has greatly improved over the years as evidenced by the increase in numbers of professional publications, scientists pursuing companion bird research and continuing education opportunities. In the United States, the Association of Avian Veterinarians (AAV) began in 1980 as a group of 175 veterinarians. Today, membership tops 3300 veterinarians from 43 countries.5 The explosion of new information, treatment and surgical protocols provides opportunities to practice avian medicine at very high levels. This also represents a double-edged sword, as those wishing to provide veterinary care for companion birds must be willing to practice at this advanced level and stay abreast of the current standard of care. It is no longer acceptable for veterinary professionals to proclaim the pet to be "just a parakeet" and inform the owner there is not much that can be done.

In 1993, the American Board of Veterinary Practitioners established a board specialty for avian practice, with rigid requirements for certification. In 2002, there were 92 board-certified avian specialists in 22 states, and in Canada and the Netherlands.1 Outside the USA, the European College of Avian Medicine and Surgery (ECAMS), established in 1993, and Australia's avian veterinary specialist program provide similar advanced degrees.8 Certified avian specialists should be viewed as a valuable resource for those desiring second opinions and referrals on difficult cases. As in any medical referral situation, human or veterinary, referring veterinarians should provide complete medical records including radiographs and laboratory results to the referral veterinarian and expect a timely response, written report and complete follow-up recommendations.

Pet Bird Ownership in the United States

The popularity of pet birds, especially psittacines, remains strong.² However, an American Veterinary Medical Association (AVMA) survey covering 1991 to 2001 showed that the percentage of households owning pet birds and the actual numbers of birds kept as pets had decreased. In that time period, numbers of birds owned as pets decreased from 11 to 10.1 million.⁴ According to most recent statistics, more than half of USA households own a companion animal, and of these households, approximately 4.6% own pet birds. Yet another survey covering 2001 to 2002 by the American Pet Products Manufacturing Association (APPMA) showed 6.9 million homes owned a bird. This survey conflicts with data generated by AVMA and actually reports the number of households owning birds as slightly increasing.

Birds remain the most popular specialty or exotic pet, second only to fish. As a comparison, less than 2% of households owned pet rabbits. All other exotic pets surveyed, including ferrets and reptiles, were well below one half of 1%. Practitioners seeing even modest numbers of pet birds will affirm APPMA statistics proclaiming the cockatiel as currently the most popular pet bird species in the USA (Table 2.1).

Bird ownership was strongest in the Pacific and Mountain regions of the USA in 2001, while the lowest percentage of bird owners lived in the West, North and Central regions.

Table 2.1 | Numbers and Types of Avian Patients Seen in 1 Year at a Busy Avian Practice¹⁶

Jenday	7	Yellow-collared	8	Flock consult	39

Typical pet bird owners do not fit a general profile, although a few statistical generalizations can be made. More owners are couples rather than single, and the majority have at least two children. Personal income does not seem to influence the likelihood of bird ownership, but level of education apparently does. Persons with advanced college degrees are much *less* likely to own pet birds. Bird owners are slightly more likely to live in urban rather than rural areas. Therefore, the "typical" bird owner in the USA may be a young couple with undergraduate college degrees, with two children, living in a large metropolitan area with a single pet bird.

Companion bird ownership appears to be popular outside the USA as well. In Australia, pet bird ownership apparently is even more popular as approximately 17% of households own a bird, with an average of 8.7 birds per household (R. Doneley, personal communication).

Frequency of Veterinary Care

The AVMA survey indicated both good and bad news for avian practitioners. On the negative side, pet bird owners overall are not likely to seek veterinary care. In 2001, only 11.7% of bird owners in the USA reported at least one veterinary visit. In comparison, 83.6% of dog owners and 65.3% of cat owners reported at least one veterinary visit in 2001. On the positive side, however, a 6year survey indicated the average number of veterinary visits for pet birds actually increased. An estimated 2 million avian veterinary visits occurred in 2001, compared to 1.6 million in 1996. This represents a solid increase in demand for the services of avian veterinarians. More evidence for this conclusion can be seen in the fact that veterinary expenditures for bird owners increased dramatically from 37 million dollars in 1991 to 135 million dollars in 2001.

It is interesting to note those veterinary services most commonly purchased for pet birds. Examinations are purchased most frequently, followed by laboratory tests, then emergency care. In comparison, emergency care is not even listed in the top five services most commonly purchased by dog and cat owners. This does not suggest that emergency care for dogs and cats is uncommon. However, it does support what many avian practitioners already suspect. While many bird-owning clients appreciate the value of preventive medicine, far too many others consult the avian veterinarian only in time of medical crisis.

Slightly more than half of surveyed clients selected their regular dog and cat veterinarian to provide care for their

Fig 2.1 | While undoubtedly popular, birds like canaries and finches are not presented as frequently for veterinary care as are birds more likely to bond with their owners.

avian pets. Encouragingly enough, 24.2% made their selection based on the fact that the veterinarian was a bird specialist. (Note that this survey does not distinguish between veterinarians who are board-certified specialists and those claiming a "special interest" in avian medicine). Discouragingly, just as many clients chose a veterinarian based simply on location.

It is obvious avian practitioners have a great deal of work to do to catch up to our fellow dog and cat practitioners. While bird owners who do seek regular veterinary care are generally seeking a higher quality of care and more frequent visits for their pets, it is obvious the great majority of bird owners either are unaware such services are available or not convinced of their value.

The Human-Bird Bond

There is no doubt that many owners develop a deep attachment to their birds, due in part to their relative longevity. A recent survey of bird-owning clients of a busy avian practice revealed that most owners consider their pets equal in importance to family members.11 This must be contrasted, however, to the growing problem of unwanted birds, to which organizers of parrot rescue facilities can readily attest. Human-bird interaction studies indicate that birds play many of the same roles for people as do dogs and cats. Some significant differences between human-bird and human-dog/cat interactions exists. More effort is required by the bird owner to elicit a positive response from their pet. Birds require more time to train than dogs and cats and lose pet quality faster when there is no regular interaction. It has been theorized that birds may be a more consistent stimulus for calming interaction than other pets, as owners must approach birds in a quiet, non-threatening manner to maintain a satisfying relationship.6 Birds that require less

interaction and typically do not bond to owners, like finches and canaries, are less often seen by veterinarians (Fig 2.1).¹⁶

Pet Loss, Grieving and Euthanasia

Most owners bonded to their pets go through a grieving process of variable intensity in the face of loss of their pet. Many choose to be present with their bird during euthanasia. This necessitates that the avian veterinarian be competent and comfortable with an anxiety and painfree euthanasia process. In 2000, AVMA published a guide to humane euthanasia techniques for many pet species. Included in the list of acceptable techniques for birds was thoracic compression.15 The AAV responded with an editorial requesting this technique be stricken from the list. In most situations, euthanasia can be best accomplished by first inducing general inhalant anesthesia. Euthanasia solution can subsequently be administered by intravenous injection. This technique, performed in a quiet, private area with veterinary personnel relating to the patient in a gentle, compassionate manner, is usually gratefully accepted by grieving owners.

The same survey of pet bird owners mentioned above indicated that the majority of owners would, in the event of the death of their pet bird, choose private burial on their own property. A surprising number, however, stated they would select individual cremation with return of ashes.¹¹

Very few owners indicated they had provided for their pet in a formal or legal will in the event of their own death. The great majority of owners, however, said they had already discussed the possibility and made informal arrangements for continued care of their pet.¹¹

History of Pet Bird Ownership

The literature is full of tantalizing, although not completely documentable, references to pet parrots in history. The earliest reference may be Ctesia's *Indica*, which contains a reference to a bird resembling a plumheaded parakeet (*Psittacula cyanocephala*). Aristotle gave the name Psittace to a similar bird he described. Frederick II (1194-1250) was said to enjoy the company of an umbrella cockatoo given to him by the Sultan of Babylon. In 1492, Columbus brought back a pair of Cuban Amazons to Queen Isabella of Spain. The first sighting of an Australian bird by a European was said to

be on August 22, 1699, when William Dampier spotted a flock of little corellas off the northwestern coast of Australia. A reference on Aztec burial customs reports the burial of a prince together with a macaw. It is fascinating to consider the improbable relationship of the stereotypical pirate and his pet parrot.

Regulations Concerning Pet Birds

While regulations exist in the USA prohibiting the ownership of some native wild birds, there are few restrictions concerning pet bird ownership. Some communities prohibit the keeping of birds that are considered to be farm animals, such as geese and chickens. Some apartment dwellings and condominiums include birds in pet ownership restrictions. International trade in birds for the pet trade, however, is regulated by the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES). CITES is an international agreement between governments to ensure that trade does not threaten the survival of wild animals and plants. CITES entered into force in 1975 and includes over 150 participating governments protecting approximately 5000 species of animals and 25,000 species of plants. Since the adoption of CITES, not a single protected species has become extinct as a result of international trade. Protected species are classified into three Appendices, listed I, II and III. Appendix I species are threatened with extinction, and trade is prohibited with exceptions made for specific circumstances, such as scientific research. Appendix II species are not threatened but may become so if trade is not restricted. Trade in these species must be approved and an export permit granted. Appendix III species may be legally traded, but are listed in order to solicit cooperation of other countries to ensure trade is not unsustainable. Specific permits also are required.

Under the classification Psittaciformes, 44 species are listed under CITES Appendix I, including 13 Amazon and 6 macaw species. Within the USA, CITES is enforced by United States Fish and Wildlife Service division of Management Authority. Legal importation of CITES I-, II- and III-listed species to the USA officially ended in 1993 with passage of the Wild Bird Conservation Act. Birds legally imported to the USA prior to this act still may bear an import band placed at the time of entry into a USA quarantine station. Quarantine bands are easily recognized and are imprinted with three letters and three numbers. Once birds leave quarantine, there is no legal requirement to retain the band, and most have since been removed. Domestically bred birds are commonly

Fig. 2.2 | The solid aluminum breeder band is often inscribed with letters (breeder and state) and numbers (year of birth and ID number) The "TX" means this bird was bred in Texas.

close-banded within weeks of birth. (Fig 2.2) Closed bands are difficult to remove. They have no legal meaning other than identification. Using one of these bands to trace the origin of a bird is nearly impossible.

Although illegal importation exists, the proliferation of large corporate and small "backyard" parrot breeders supplies the pet trade with an ample number of birds at reasonable prices. Many breeders place a band on their birds when they are very young. Breeders may inscribe bands with any combination of symbols. A typical breeder band may contain a set of letters identifying the breeder, a two-letter combination indicating state of hatch, and two numbers signifying year of hatch. Interstate movement of any bird, including pet birds vacationing with owners, requires a state-issued health certificate completed by a licensed and accredited veterinarian indicating the bird is free of signs of illness. In addition, the destination state may require additional testing before the bird can cross state lines. Requirements are obtained by phoning the destination state's Board of Animal Health, or looking up requirements on each state's individual web site. That being said, many owners are oblivious to these regulations and do not request health certificates when they travel.

The destination country similarly determines requirements for entry into foreign countries. Most countries require the bird to be identified with a leg band or microchip. Requirements can be obtained by phoning the consulate office of the destination country. In the USA, international requirements can be obtained by calling the local US Department of Agriculture-Animal and Plant Health Inspection Service office (USDA-APHIS). Alternatively, requirements are posted on the USDA-APHIS web site, which also contains information for traveling with birds into the USA from foreign countries.¹⁷

Fig 2.3 | The Endangered Species Act forbids the keeping of Queen of Bavaria (or golden) conure (*Aratinga guarouba*) for commercial purposes. Feather picking is common in this species.

Fig 2.4 | Moluccan cockatoos (*Cacatua moluccensis*) appreciate human attention, even if it means wearing a costume.

The movement of CITES-protected species is not regulated within the USA; however, international travel with these species requires a special permit. Information on travel from the USA with CITES-protected species may be obtained from the United States Fish and Wildlife Service (USFWS).⁹

The Endangered Species Act was passed in 1973. This act is enforced by USFWS, which regulates commerce concerning endangered species. Any bird listed as threatened or endangered may not be traded in interstate commerce. The Queen of Bavaria or golden conure (*Aratinga guarouba*) is listed as endangered as well as several other species occasionally seen in pet practice (Fig 2.3). Under the provisions of the Endangered Species Act, these species may not be sold in interstate commerce or kept for commercial purposes. Government regulations concerning companion birds are further discussed in Chapter 1, Clinical Practice.

Birds in Schools and Care Facilities

Birds are gaining in popularity in nursing homes and other care facilities. Birds most commonly seen in care facilities are canaries, budgerigars, cockatiels and lovebirds (Fig 2.4). Many studies suggest the benefits of birds and other animals in care facilities. One experimental study documented better attendance and less hostility in group therapy meetings of psychiatric patients in rooms containing finches. Local health departments may require veterinary examinations and periodic testing for animals in contact with residents. Veterinarians performing these exams must be aware they cannot certify that any bird is completely free of

potentially zoonotic diseases, in particular, chlamydiosis (see Chapter 27, Update on Chlamydophila psittaci: A Short Comment). Facility and health department personnel, along with the veterinarian, must determine a reasonable amount and frequency of testing to minimize health risk due to the presence of pet birds, especially in the presence of persons with diseases compromising the immune system. New additions should be guarantined away from existing birds and residents for at least 45 days.9 Attention must be given to proper cage construction, dietary requirements and cage additions, such as perches and toys. Birds in care facilities occasionally are subjected to multiple caregivers, or are in the care of persons with no training or interest in their well-being. Caretakers must receive adequate training in all aspects of care of their charges and be familiar with common signs of illness.

Birds and Animal Welfare

Many well-known animal welfare groups have taken stands for and against pet bird ownership. In 2002, the American Society for the Prevention of Cruelty to Animals (ASPCA) proclaimed January as "Adopt a Rescued Bird Month." The ASPCA web site contains links to a directory of birds available for adoption and worthy information on the pros and cons of pet bird ownership. People for the Ethical Treatment of Animals (PETA), an organization known for aggressive animal rights positions, encourages formulated diets and regular veterinary care for pet birds. The same organization, however, advises against any captive breeding of parrots and encourages owners to allow pet birds to select a companion bird of its own species and to free fly. The Humane Society of the USA, the largest animal welfare

 $\textbf{Table 2.2} \;|\; \textbf{G}eneral \; \textbf{G}uidelines \; \textbf{for Recommended Pet Birds Based on General Pet Quality}$

Common name and/or representative species	General traits	Potential concerns		
African Grey - Congo (Psittacus erithacus)	The most demonstrably intelligent psittacine sp. Greatest potential for range of vocalizations and increasing vocabulary throughout their lives. Research has documented cognitive association between learned words and both actions and objects.	associations with people and objects that may develop into phobias/neuroses. Feather destruc- tive behavior is a very common condition in cap- tive African greys.		
African Grey - Timneh (<i>Psittacus e. timneh</i>) (Darker grey and smaller than the nominate Congo species)	Similar in appearance and characteristics to the nominate species noted above.	Both positive traits (learning ability) and negative traits (neurosis, obsessive behavior) are usually somewhat reduced in this subspecies compared to the nominate species.	ow	
Amazons (Amazona spp.) • Yellow-naped (A.ochrocephala auropalliata) • Blue-fronted (A.aestiva) • White-fronted (A.albifrons) • Orange-winged (A. amazonica) • Mealy (A.farinosa) • Festive (A.festiva)	Active, fairly hardy. Tend to become bonded to certain individuals and aggressive toward others. Some are excellent talkers (eg, yellow-nape, double yellow-head, blue-fronts).	Screaming, territoriality, and aggression are common. Learn quickly to use lunging or biting to relay their negative opinions. Quieter species include: spectacled (white-front) orange-winged, mealy, festive		
Budgerigars (Melopsittacus undulatus)	Can be interactive, enjoyable pets.	Genetic predisposition to many diseases and neoplastic conditions.	ow	
Caiques (Pionites sp.) Black-capped (P. melanocephala) White-bellied (P. lucogaster)	Beautiful, small parrots, playful personalities	Although difficult to locate, this genus is a favorite recommended species. Not known for their talking ability.	NW	
Cockatiels (Nymphicus hollandicus)	Intelligent, popular pets. Can become very attached to the owner or to conspecifics.	Chronic egg-laying in some females. Aggression may develop in males as they mature (especially toward children). Color mutations may be more prone to illnesses.	ow	
Cockatoos general (Cacatua sp.)	Enjoy physical contact. Vocabulary is limited but intelligible and often endearing.	Screaming, mate aggression (conspecific or surrogate) may be severe. Occasional unpredictable severe biting episodes, even with humans to which they are bonded. (Note: Powderdown production is pronounced, and is not only a cleaning concern, but can cause allergic reactions in some people and in some macaws)	ow	
 Smaller Cacatua sp. Goffin's (C. goffini) Red-vented (C. haematuropygia) Bare-eyed (C. sanguinea sanguinea) 	More active than other, larger cockatoos.	Can be hyperactive. Not as predictably accepting of cuddling and petting.	OW	
Larger Cacatua sp. • Umbrella or white cockatoo (C. alba)	Enjoy cuddling, petting, and prolonged physical contact.	Can develop behavioral and medical problems, (screaming, feather destructive behavior, self- mutilation, vent prolapse) related to their demand for physical stroking and/or other psy- chological captive abnormalities.	OW	
Moluccan or salmon-crested cockatoo (C. moluccensis)	As with umbrellas, but can be less predictable and even aggressive.	Often escape artists. Behavior problems, as with umbrella cockatoos above, can occur. May be very destructive with their beaks.	ow	
Conure (Aratinga sp.) • Sun (A. solstitialis) • Jenday (A. jandaya) • Gold-capped (A. auricapilla)	Beautiful, intelligent birds.	Loud, high resonance screams. Can become territorial. Not known for their talking ability.	NW	
Conure • Nanday (Nandayus nenday)	Historically, were common imports and relatively inexpensive. Captive-raised individuals can make excellent pets.	Established feral colonies of nanday conures exist in parts of south Florida. May develop loud and persistent screaming behavior.	NW	
Conure • Patagonian (Cyanoliseus patagonus)	Beautiful, larger conure. Relatively quiet.	Historical documentation as carriers of Pacheco's disease virus has made owners wary of introduction into their collection. This may still be a valid concern in multiple-bird households.	NW	
Conure (Pyrrhura sp.) Green-cheeked (P. molinae) Black-headed (P. rupicola) Maroon-bellied (P. frontalis)	Green-cheeked (<i>P. molinae</i>) conures.		NW	
Doves, Pigeons (Columbiformes)	Gentle, excellent pets. Although the degree of interaction (vocal, body posturing) is limited, there is little or no danger of injury to humans from bites.	If raised by humans may have no fear or defense against dogs or cats	OW NW	
Clectus sp. (ten subspecies) Red-sided (E. roratus) Vos (E. vosmaeri) Solomon Island (E. solomonensis)	Most pronounced sexual dimorphism of any psittacine. "Pensive" when considering novel items or situations in a secure environment, leading to the misconception that eclectus are dull-witted. Moderately good talkers. Males tend to be more docile than females.	Unless socialized early, may become alarmed by new situations or locations. Feather destructive behavior common. In breeding situations, females will often traumatize males.		
Finches, Canaries (Passerines)	Easy to care for, quiet, pleasant vocalizations. Limited ability to interact with their owners as	Inbreeding has created genetic predispositions to multiple disease syndromes in some lines.	OW	

Chapter 2 | THE COMPANION BIRI

Table 2.2 | General Guidelines for Recommended Pet Birds Based on General Pet Quality

Common name and/or representative species	General traits	Potential concerns	
Hyacinth macaw (Anodorhynchus hyacinthinus)	Largest psittacine. Beautiful bird. Temperament can be calmer than other macaws. The attending veterinarian needs to be aware of specific nutritional needs and pharmacologic sensitivities.	Possibly due to genetics or captive rearing limitations, this species can become neurotic/phobic. Research into the parents' temperament is recommended. Expensive.	NW
Lories and Lorikeets Rainbow (Trichoglossus haematodus) Red (Eos bornea) Dusky (Pseudeos fuscata)	Ring-necks and lories were previously considered aviary birds, but can be quite tame when captive raised. Beautiful colors and brilliant sheen to feathers.	Fruit and nectar diet makes droppings messy. As with Aratinga sp, their beak sharpness and their speed make bites, if they occur, painful.	ow
Lovebirds (Agapornis sp.) • Fischer's (A. fischeri) • Peach-faced (A. roseicollis)	Can be very tame and bonded to people or other birds.	Can be very aggressive during breeding season.	ow
Macaws (Ara sp.) • Blue and gold (A. ararauna) • Green-winged (A. chloropterus) • Scarlet (A. macao)	Large, physically active, vocal birds. Intelligent, highly interactive and energetic. Require frequent training and structured play to focus their energies.	Need physical outlets for their abundant energy. Loud; screaming can become a problem. Generally develop a limited vocabulary. Learn tricks readily. Require a knowledgeable owner.	NW
Mini-macaws • Yellow-collared (Ara auricollis) • Noble (A. n. cumanensis) • Severe or chestnut-fronted (Ara severa)	Can be excellent, affectionate and intelligent pets.	Common as imports in previous decades. Few were bred in captivity following cessation of importation. Therefore the current availability is low and the genetic pool is limited for many species.	NW
Mynahs • Indian hill mynah (Acridotheres tristis)	Excellent mimics. Have the same interactive limitations as the small passerines.	Stools are projectile and messy. Prone to iron storage disease.	ow
Grass parakeets (Neophema sp.) • Bourke's (N. bourkii) • Turquosines (N. pulchella)	Quiet, easily maintained birds, often kept in aviaries.	Not as readily bonded to people as many other parrots.	ow
Pionus sp. Parrots • White-headed (P. seniloides) • Bronze-winged (P. chalcopterus) • Dusky (P. fuscus)	Usually gentle, smaller and quieter than the related Amazons.	Generally, limited ability to mimic speech compared to Amazons. Produce a rapid "sniffing" sound when frightened that is often mistaken for respiratory disease.	NW
Poicephalus sp. Parrots • Senegal (P. senegalus) • Myers (P. meyeri)	Playful, active, usually gentle, fairly hardy.	Can become territorial with sexual maturity.	OW
Quaker parakeet (Monk) (Myiopsitta monachus)	Intelligent, feisty birds, with moderate talking ability. Hardy, including tolerance of colder environments. Colony breeders.	Can become aggressive. Tendency to become obese and a relatively high incidence of pancreatic problems. Illegal in some US states due to their propensity for establishing feral populations, even in temperate climates.	NW
Ring-necked Parrots (Psittacula sp.) • Mustached (P. alexandri) • Derbian (P. derbiana)	ustached (<i>P. alexandri</i>) Were previously thought to be "aviary birds" bility. Some new color mutations may be		ow
Toucans (Ramphastos sp.) • Keel-billed (R. sulfuratus) • Toco (R. toco) • Channel-billed (R. vitellinus)	Beautiful, fascinating birds. Recognize owners, but limited interaction (may "clack," but do not mimic speech or posture as do psittacines).	Dietary requirements can be difficult to fulfill, including low iron and some live prey. Prone to iron storage disease. Voluminous, messy stool.	NW
Waterfowl Geese (Anser sp.) (Branta sp) (Nettapus sp.) Ducks, mallard (Anas platyrhynchos) Muscovy (Cairina moschata)	Usually gentle, may be aggressive during breeding. Outdoor environment highly recommended.	Require water for swimming/bathing/drinking. Voluminous stools	NW OW
Waterfowl Swans (Cygnus sp.)	Beautiful, but often aggressive.	Not usually tame as adults	

Note: Since disease susceptibility (eg, circovirus and sarcocystosis), nutritional needs and/or dietary sensitives may be dependent upon the area of origin, Old World (OW) vs. New World (NW) is noted in the final species column.

organization in America, considers only canaries, finches, budgerigars, lovebirds and cockatiels suitable as pets. Larger birds are not recommended, and reasons stated against ownership include longevity, specialized needs and demands for care.¹⁰

The Ideal Pet Bird

While opinions vary on what constitutes the ideal pet bird, Table 2.2 lists commonly kept birds and some of their characteristics relating to pet qualities (Figs 2.5-2.45).

Selective Breeding, Color Mutations and the Future of Companion Birds

Selective breeding has produced a variety of desirable physical and behavioral traits in many species of companion animals. Along with these desirable traits, however, come some that are less desirable or even detrimental to the health of the animal. So-called "puppy mills" in the USA in the 1960-1970s produced large numbers of dogs for the pet market without regard to the quality of animals produced. Practitioners are beginning

to recognize this phenomenon in pet birds, particularly cockatiels (Figs 2.36, 2.37), lovebirds (Fig 2.42) and budgerigars (Fig 2.45). Anecdotal reports indicate these mass-produced birds have an increased incidence of disease, unthriftiness and shorter life spans. In some cases, mass-produced birds are given prophylactic antibiotic and antifungal medications without a medical diagnosis. Pathogen resistance is a clear risk with this practice. Many bird breeders are producing new and novel color mutations of common species. Unusual varieties of cockatiels, budgerigars and lovebirds have been available for many years. Avian practitioners now are seeing unusually colored Quaker parrots and conures as well. Whether or not these mutations are less healthy than their normal counterparts remains to be determined.

An unusual color variation has been seen in African grey parrots. These birds fledge with or later develop pink or red contour feathers over various portions of the body (Fig 2.46). This coloration has been linked to circovirus or a dietary imbalance (see Chapter 4, Nutritional Considerations, Section II and Chapter 13, Integument). Many of these birds, however, do not appear to develop other clinical evidence of illness.

Selecting Healthy Pet Birds

The average pet owner has at least a few choices with regard to selection of a pet bird. The ideal source is a breeder with limited numbers of hand-reared offspring of just a few species. For purposes of disease control, the ideal breeder does not raise larger psittacines in the same premises as smaller birds such as cockatiels, lovebirds and budgerigars. The ideal breeder selects for characteristics that maximize pet quality, such as calmness

Table 2.3 | Summary of Characteristics of Breeders of Parrots for the Pet Trade

Ideal	Not Ideal
Raises small numbers of birds	Raises many birds
Specializes in a few species	Many species intermixed at same facility
Does not mix larger parrots with small species, such as cockatiels, lovebirds and budgerigars	Larger hand-fed parrots mixed with smaller species
Selects breeders to maximize ideal pet characteristics	Breeders selected for reasons other than to maximize ideal pet characteristics: only birds avail- able, "bargain birds," unwanted pets with problems such as phobias and feather plucking
Sells only weaned, hand-fed parrots	Sells unweaned young birds
Sells birds directly to clients, and not through pet stores or bird fairs	Sells birds through venues where young birds are co-mingled: pet stores and bird fairs
Raises birds on pellets	Raises birds on seeds

and docility and spends significant amounts of time raising and socializing young birds and feeds a formulated diet (Fig 2.47). The ideal breeder consults with an avian veterinarian and may offer birds that have been examined or even screened for underlying disease conditions. Table 2.3 summarizes the ideal characteristics of breeding facilities that produce parrots for the pet trade. In many cases, the only source of birds available locally may be those found in pet stores or bird fairs. Buyers must be aware of the potential for disease when unweaned young birds from varying sources are mixed together. Buyers should question bird vendors carefully and obtain a health guarantee. Not all health guarantees are alike and should be examined carefully. Some guarantees offer to pay veterinary bills if a health problem is discovered within a certain time period. Some merely offer to replace the ill bird with another from the same source, which often is unsatisfying to purchasers who may quickly bond to their new pet.

Increased computer access has allowed people to search for and purchase parrots over the Internet. While purchasing birds in this manner has many advantages, disadvantages include potentially shipping young birds long distances and in some cases, the inability to fully scrutinize the source.

Many commercial hatcheries produce healthy ducks, chickens, geese and other exotic fowl that can be purchased in small numbers for the pet trade. These facilities tend to follow strict disease prevention protocols, and often are much safer sources than backyard breeders or animal auctions (see Chapter 21, Preventive Medicine and Screening).

Comments on Life with Birds

Sharing life with pet birds is not for everyone. Experienced bird owners understand that birds can produce a great deal of dust, dander and mess, require constant handling to remain tame and in many cases are long-lived. Many birds naturally tend to dunk food into water bowls and shred toys into tiny bits. Some owners can be frustrated by the demands of pet birds and endless cleaning routines. Overall, birds require more intensive training to remain social than do most dogs and cats. A well-cared-for parrot may live for many decades.

All parrots make noise, and while this fact doesn't seem to bother parrot lovers, it can bother many neighbors. It's important to find out in advance if the noise is likely to cause problems. Sometimes the quiet but constant beeping of a cockatiel may be more offensive than the

Fig 2.5 | The human/avian bond can occur with common birds, such as pigeons (Columba livia).

Fig 2.6 | Doves, such as this pied ringneck dove (*Streptopelia risoria*), are gentle and quiet.

Fig 2.7 | Often overlooked as pets, some chicken breeds may be good pets for children.

Fig 2.8 | The rose-breasted cockatoo or galah (*Eolophus roseicapillus*) is considered a pest in its native Australia, where freeranging birds are captured for the pet trade.

Fig 2.9 | The black palm cockatoo (*Proboscigar aterrimus*) is a rare, expensive and endangered species that is uncommon in captivity and seldom seen in clinical practice.

Fig 2.10 | These pied Bengalese (or society) finches (*Lonchura domestica*), while commonly kept as pets, are also used as foster parents to chicks of more exotic finch species.

Fig 2.11 | The appealing cordon bleu finch (*Uraeginthus* spp.) has become expensive due to bans on wild-caught birds and aviculture challenges.

Fig 2.12 | The yellow-collared macaw (Ara auricollis) is one of the so-called "mini" macaws that exhibits characteristics similar to larger macaws but in moderation.

Fig 2.13 | Like most mini macaws, this severe (or chestnut-fronted) macaw (Ara severa) can be hard to find, because breeders are often few in numbers.

Fig 2.14 | Although this white phase scarlet macaw (Ara macao) is rare and valuable, mutations like this are often less resistant to disease.

Fig 2.15 | Green-winged macaws (Ara chloroptera) are beautiful and gregarious, but they need special homes because of their size, noise level, destructive habits and demand for attention.

Fig 2.16 | The blue and gold macaw (Ara ararauna) is the most common macaw species kept as a pet in the United States.

ro Parque

Fig 2.17 | The caninde (or blue-throated) macaw (Ara glaucogularis) is smaller than the blue and gold macaw and is rarely seen in captivity.

Fig 2.19 | Despite the initial investment to purchase, it is not uncommon for the hyacinth macaw (*Anodorhynchus hyacinthinus*) to be moved from home to home due to the great demands of upkeep.

Fig 2.21 | The white-fronted Amazon (Amazona albifrons) is one of the few sexually dimorphic parrots; red feathers are found on the wings of the mature male and not on the female.

Fig 2.18 | The spix macaw (*Cyanopsitta spixii*) is the rarest macaw and likely no longer exists in the wild.

Fig 2.20 | The military macaw (Ara militaris) is often confused with the Buffon's macaw, but is slightly smaller and equally rare in captivity.

Fig 2.22 | The blue-fronted Amazon (Amazona aestiva) is probably the most popular Amazon parrot because of its gregarious nature and ability to mimic, but like the larger Amazons, is frequently abandoned to a rescue facility.

Fig 2.23 | The double yellow-headed Amazon (Amazona ochrocephala oratrix) is one of the least commonly seen Amazon parrots due to depletion in the wild and their aggressive personalities in captivity.

Fig 2.24 [Yellow-naped Amazons (Amazona auropalliata) are successfully bred in captivity and are popular pets because they are entertaining talkers, singers and clowns.

Fig 2.25 | Some communities have banned the Quaker (or monk) parakeet (*Myiopsitta monachus*) because escapees have established free-ranging breeding colonies even in temperate climates.

Fig 2.26 | While the black-headed caique (*Pionites melanocephala*) is recommended as a pet, it is relatively rare and hard to find.

Fig 2.27 | The white-bellied caique (*Pionites leucogaster*) may be threatened with extinction in the wild and should not be kept as a single pet.

Fig 2.28 | Small Australian parrots, including the superb parrot (or barraband parakeet) (Polytelis swainsonii), are usually viewed as aviary birds. However, if an individual is hand-raised in a family environment, it can be a good pet.

Fig 2.29 A dusky-headed conure (Aratinga weddellii) is considered an ideal parrot because of its size, temperament, hardiness, lack of mutations and potential for human bonding.

Fig 2.30 | Maroon-bellied conures (Pyrrhura frontalis) are smaller and generally more acceptable as a pet than the slightly larger Aratinga species.

Fig 2.31 | The sun conure (Aratinga solstitialis) is one of several conure species that are commonly bred in captivity, but even hand-raised individuals are loud and somewhat aggressive.

Fig 2.32 | Blue-headed pionus parrots (*Pionus menstruus*) are noted for their calm behavior and quiet nature, but are subject to stress-related disorders.

Fig 2.33 | Although infrequently seen in practice, pionus parrots (*Pionus* spp.) represent ideal pet characteristics: predictability, reserved nature, quiet, tidy, gentle and tolerant.

Fig 2.34 | In the USA, African grey parrots (Psittacus erithacus) are being domestically bred and managed to eliminate negative characteristics that are still prevalent in imported greys in Europe: feather-picking, screaming and respiratory infections.

Fig 2.35 | Eclectus parrots (*Eclectus roratus*) are the most pronounced example of sexual dimorphism: the female is red and the male is green. Eclectus appear to have some unique disorders that are not yet fully understood.

Fig 2.36 | The cockatiel (Nymphicus hollandicus) is the most common patient seen by avian veterinarians. A male is shown. For best results a cockatiel should be purchased from a reputable breeder with less emphasis on developing color mutations.

Fig 2.37 | The popularity of cockatiel color mutations brings an increase in disease and unthriftiness. Lutinos (with reddish eyes) seem to have immune deficiencies and short lives, whereas pieds (such as this pied white-faced cockatiel with dark eyes) have fewer health problems.

Fig 2.38 | The meyer's parrot, a member of the Poicephalus genus, can be an enjoyable pet.

Fig 2.39 | Because of their bright colors and clown-like antics, lories (*Loricus* and other species) in general are appealing, but their traditional nectar diets result in loose, messy droppings. This particular species, the black-capped lory, is rare and thus should not be kept as a pet.

Fig 2.40 [The Bourke's parrot (Neophema bourkii) has all the same characteristics as other Australian small parakeets and is becoming more popular as an aviculture bird because of mutations, such as this rosy Bourke.

Fig 2.42 [Lovebirds (Agapornis spp.) are best obtained from a reputable breeder who has not concentrated on developing mutations and has paid more attention to their long-term health. Many breeding birds have endemic circovirus.

Fig 2.44 | Creating color mutations, such as this lutino ring-necked parakeet, result in weaker birds with more health problems.

Fig 2.41 |Toucans can be entertaining clowns but are not generally recommended as pets because of their special dietary and large housing requirements.

Fig 2.43 | The hardy Indian ring-necked parakeet (*Psittacula krameri*) is a common pest bird in its native India. It is dimorphic: the male has a distinct ring around the neck, whereas the female's ring is not a full collar.

Fig 2.45 | The budgerigar (*Melopsittacus undulatus*) is the most popular pet parrot in the world. Budgerigars bred for show are often grossly overweight and have reduced life spans. The wild-type green color reflects sexual dimorphism: the cere is blue in males and brown in females.

Fig 2.46 | Unusual red-colored feathers in African grey parrots may be linked to a dietary deficiency or circovirus infection. In many cases, however, these birds remain apparently healthy.

Fig 2.47 | Weaning a budgerigar to a formulated diet often is easier using a mirror. Seed diets are the major cause of illness in pet birds.

occasional yell from Amazons. Canaries, pigeons, doves, finches, and even female ducks and chickens have been found in homes where neighbors never suspected they lived. In many cases, as far as neighbors are concerned, the best bird is a quiet bird.

Appropriately sized cages can take up considerable space, especially for larger birds. Large cages, play gyms and toys can be prohibitively expensive. Some owners seek to cut costs by buying used cages, which may not be safe if the previous inhabitant died of a communicable illness. Wooden perches and porous items cannot be properly disinfected and should not be reused.

Pets often are restricted for owners living in apartments or condominiums. However, one ingenious owner rescued a boisterous Moluccan cockatoo, took it to the swimming pool and put it on the fence, declaring the bird to be the condo mascot. While the condo had a nopet rule, regulations apparently did not cover mascots.

Medical care for birds tends to be less expensive than that for other domestic species. An example was heard on National Public Radio program update on veterinary costs for pets entitled, "How Much is that Doggie in the Window?" The woman interviewed had just spent over \$20,000 to treat her cat for cancer. Although many avian vets have never come close to that sum with a sick bird, the interviewee's expenditure may have been due to her inability to let go of her pet and not reflective of an expensive but successful treatment protocol.

With the above in mind, many things must be considered before acquiring a pet bird. The biggest birds do not automatically make the best companions. Most of the birds that these authors generally recommend are medium to small birds, which are easier to manage, house, feed and train than are large psittacines. While beauty is in the eye of the beholder, the finches and small parrots often are the most ornate. If song is most inspiring, only one bird has held the title of "Elvis of Birds" for so long: the humble canary. In many cases, for beauty, size and song, one has to look no further than to the tiniest birds to fulfill many desires.

So why does one choose to cohabit with a bird? It generally comes down to what seizes a person's heart. For some people, birds fill the void in a way no other pet can.

Conclusion

Avian companions clearly occupy more than just a niche in their caregivers' homes and lives. The importance and expertise of avian medical practice must continue to expand to meet the demands of this multi-species discipline. Bird ownership increasingly embraces large and small companions, where value often is not related to the cost of the bird. The proliferation of birds in other non-home settings, debates regarding animal rights and the wide variety of opinions generated by these issues will continue to occupy avian medical practitioners and caregivers alike.

The Natural Science of Behavior

SUSAN G. FRIEDMAN, PhD; THOMAS M. EDLING, DVM, MSpVM; CARL D. CHENEY, PhD

Of all the many facets of parrots' total wellness supported by veterinarians, perhaps the most challenging of all is behavior. Having adapted over eons for survival in the free-range environment, many parrot behaviors run counter to those necessary for success in our homes. This challenge is intensified by parrots' extraordinary ability to learn maladaptive behaviors from their oftenunwitting caretakers. Veterinarians also face educational challenges as their pursuit of a comprehensive and cohesive knowledge of behavior often is made difficult by the fractured development of the science itself — the natural science of behavior historically crosses two disciplines, zoology and psychology, each with its own purpose and methods. Finally, among professionals and laypersons alike, there is a general lack of awareness that a science of learning and behavior exists within the field of psychology. A sound understanding of this science, known as behavior analysis, is critical to successfully keeping parrots as companions. These challenges contribute to the current state of affairs in which too many pet parrots unnecessarily fail to thrive due to behavior problems.

In this chapter, we provide the foundation for a comprehensive and cohesive understanding of behavior as it relates to facilitating the lives of companion parrots. To meet this goal, the following topics are discussed: freerange behaviors as a basis for predicting and interpreting the behavior of parrots in captivity, a simplified model for systematically analyzing the functional relationships between behavior and environmental stimuli, and the teaching technology based on the fundamental principles of learning and behavior. With this information, veterinarians will be able to better guide their clients to proactively teach their parrots successful companion behaviors and effectively analyze and resolve behavior problems that inevitably arise.

What is Behavior?

Fundamental to all science is the task of explaining phenomena by identifying observable, physical events that produce them. This is true with behavioral science as well, where the goal is to explain behavioral phenomena. In this scientific context then, behavior is anything an animal does that can be observed and measured. This includes overt behaviors that can be directly observed by others (such as preening and eating) as well as covert behaviors, which can only be directly observed by the individual so behaving (such as thinking and feeling). As a result, covert behaviors are of limited use in our work with parrots due to their inaccessibility. And, considering the difficulty most of us have guessing what members of our own species are thinking in the absence of direct measures, accurate interpretation of parrots' covert behaviors is all the more remote.

Similarly, the practice of describing what an animal is rather than what it *does* is an obstacle to understanding and changing behavior. Labels, such as "is territorial," "is dominant," and "is spoiled," do not describe behaviors, they describe ideas. These ideas, called hypothetical psychological constructs, are largely untestable theories about mental processes believed to explain behavior. Focusing on constructs often gets in the way of identifying straightforward behavior solutions. To change behavior, clients must work with behavior directly, and they should be encouraged to move past inferences of covert behaviors and construct labels to observe and describe what their birds actually do. For example, the frequently used label "is territorial" often describes a bird that bites; "is dominant" often describes a bird that does not step up; and "is spoiled" often describes a bird that

screams for intolerable durations. Territoriality, dominance and the degree to which the bird is spoiled can't be changed directly because they have no tangible form; however, biting, stepping up and screaming are all behaviors birds *do*, which we can do something about.

Behavior is the result of the indivisible blend of heredity and learning. These two processes work toward the same end, ie, coping with environmental change through adaptation. Adaptation through heredity, phylogenetic adaptation, occurs slowly over generations at the species level. Through the process of evolution by natural selection, phylogenetic adaptation equips each species for common lifestyles in their natural habitat. Alternatively, adaptation through learning is an individual process that occurs within the short span of a lifetime. As defined by Chance, learning is a change in behavior due to experience. Learning is the astonishing mechanism that equips each individual within a species to meet life's ever-changing circumstances with rapid modifiability.

Observations from the Field

Parrots are most brilliantly adapted for the free-range environment. For example, the physiology of wings, beaks and vocal structures prepares them well for the natural behaviors of flight, nest carving and long-distance contact calls. Clearly these and many other behaviors are supported by parrots' genes and are part of their natural history. From an evolutionary perspective, the genes that enable these behaviors likely serve survival functions related to food gathering, courtship and mating and protection from predators. It is worth noting, though, that the evolutionary origins of many behaviors often are easier to hypothesize than to prove.

Ethology, a discipline within zoology, is the field of behavior science most concerned with the study of behavior patterns characteristic of different animal species as they occur in their free-range environments. More complex than reflexes, ethologists call these species-specific behavior chains "fixed action patterns." Fixed action patterns are displayed by nearly all members of a species under similar environmental conditions, with very little variability in the way in which they are performed across individuals or instances. According to Gray, these behavior patterns are fixed in the sense that the "controlling mechanisms are 'fixed' in the animal's nervous system by heredity and are relatively unmodifiable." In this sense, we call them innate behaviors.

There is some debate about how unmodifiable fixed action patterns actually are, as few, if any, behaviors can be said to be immutable or impervious to experience.

Some researchers reason that "flexible action patterns" is a more accurate description of species-specific behavior chains. For example, fledglings' flight skills certainly improve with practice, as does perching and climbing. Even simple reflexes can be modified through habituation (eg, cats²) and through sensitization (eg, blowflies²). These studies add to the evidence that heredity and learning are inextricably entwined. Nonetheless, knowledge of the behavior patterns of free-range parrots, as well as the environmental conditions that elicit and shape them, greatly increases our ability to predict, interpret and manage many parrot behaviors in captivity. For these reasons, knowledge of the free-range behavior of parrots is important to improving the care of captive birds.

SOCIAL SIGNALS

Among the many things we can learn from the behaviors of free-range birds, perhaps the most important are those that serve a communication function among parrots. This is a language very unfamiliar to many caretakers, to the detriment of their birds and themselves. In an interesting study on cross-species communication, it was found that dog pups only a few weeks old were more skillful at reading human social cues (such as pointing, looking and touching) to locate hidden food than were chimpanzees and wolf pups.¹⁵ The researchers theorize that dogs uniquely possess this skill due to the process of domestication in which communication skills with humans were selected.

Unfortunately, our parrots' current lack of domestication leaves them unprepared to innately interpret human signals. This puts the onus on us to accurately interpret their communications at the same time they are learning to interpret our signals. Observations from the field confirm that parrots have a rich and subtle communication system that involves nearly every feather on their bodies. Head, eye and neck movements, body posture, wings and tail and leg and foot gestures are all used as signals to communicate desires, intentions and general comfort or discomfort with current events and conditions.

Caretakers often misunderstand the behaviors used to communicate the boundaries of personal space, especially those that function to back intruders away. Most species of parrots use threatening stances rather than outright aggression to drive off perceived intruders in the wild, and many of these behaviors are seen in captivity as well. These behavior patterns are made up of various vocalizations and both overt and subtle movements and postures. Depending on the species, such warnings include raised nape feathers with wings slightly lifted, a raised foot held open at chest level, directed hacking motions with an open beak, and growling. By not

heeding these warnings, caretakers push parrots to escalate their message to serious biting. As a result, stress is unnecessarily increased and trust is decreased for both birds and humans. Learning to perceive, interpret and respond to these signals is essential for building relationships with captive parrots. Veterinarians can help caretakers become more astute observers of their parrots' "messages" by discussing social signals with them.

ACCOMMODATING INNATE BEHAVIORS

Other innate behavior patterns common to free-range parrots, such as loud contact calls, wood chewing, food flinging and territorial biting, can be challenging to deal with in the captive setting. Changing the environment to accommodate them to the greatest extent possible, rather than attempting to change the bird, often best manages these behaviors. For example, simply answering a bird's calls, even from another room, often deters parrots from screaming. Arranging challenging body and brain activities provides alternatives to chewing household woodwork. Offering smaller, more frequent food servings in cages fitted with aprons reduces the mess and waste of food flinging. Allowing birds to climb out of their cages when the door is opened, rather than insisting they step onto intruding hands, reduces the opportunity for biting. By keeping natural behavior repertoires in mind and arranging the environment to manage them, caretakers can focus on engaging appropriate behavior rather than disengaging problem behavior.

THE LIMITS OF LEARNING

Another important reason for clients to understand parrots' free-range behaviors is to guide the general limits of what our parrots can reasonably be expected to learn. A classic article on behavior, lightheartedly entitled "The Misbehavior of Organisms," reported the breakdown of novel trained behaviors in favor of fixed action patterns. even though food reinforcement was contingent solely on the performance of the trained responses.3 The authors called this phenomenon "instinctive drift," as they observed that raccoons tended to rub coins with their paws in a characteristic washing motion rather than deposit them into a bank; pigs tended to toss coins with their snouts in a characteristic rooting motion rather than carry them in their mouths; and chickens tended to scratch the floor with their feet in a characteristic wiping motion rather than stand still.

Instinctive drift is consistent with Seligman's continuum of preparedness, described by Chance⁶: "An organism comes to a learning situation genetically prepared to learn (in which case learning proceeds quickly), unprepared (in which case learning proceeds steadily but more

slowly), or contraprepared (in which case the course of learning is slow and irregular)." Too often, unknowing caretakers simply expect too many behaviors for which parrots are contraprepared. This occurs when, for example, caretakers insist that parrots be petted by strangers (or for some birds, petted at all), or when birds are left in cages for interminably long durations with nothing to do (from the birds' perspective). Of course, the particular limits of parrots' behavioral preparedness to learn vary greatly across species and between individuals within species; still, knowledge of species-typical behaviors observed in the free-range environment is an excellent starting point for predicting and interpreting the behavior of different species of captive parrots. It also is essential to helping clients set reasonable expectations for parrot behavior in their homes.

Applied Behavior Analysis

Ethology informs us about the behavioral norms of different parrot species in the free-range environment. While this information is important to successful companion parrot care, it is not sufficient to meet the challenges of living with captive parrots. It also is essential to have expertise in applying the fundamental principals of learning and behavior applicable to all species of animals. This is true for several reasons. First is the extent to which individuals of the same species are known to vary from one another and from expected behavioral norms: Any particular African grey (Psitticus erithacus erithacus) may exhibit the cuddly behaviors of the average umbrella cockatoo (Cacatua alba); and, any particular sun conure (Aratinga solstitialis) may be as quiet as the average dusky Pionus (Pionus fuscus). Second is the wide variability across captive environments in which companion parrots are challenged to live: Ranging from quiet, routine lives with a single caretaker to noisy, unpredictable lives full of kids and other pets, no two home environments are alike. Third, parrots' extraordinary longevity means most birds will be confronted with decades of changing circumstances for which they need to be extremely flexible learners.

When we change our focus from the species level to the individual level and from innate responses to learned responses, the natural science of behavior is (much like veterinary practice itself) a "study of one." The field of behavior science that most explicitly concentrates on the learned behavior of individuals is applied behavior analysis; it primarily is the applied science of teaching and learning, which is why it is so very relevant to companion parrots and their caretakers.

ACCOUNTING FOR BEHAVIOR

For lack of knowledge about the fundamental principles of learning and behavior, many people are utterly baffled by the things their parrots do. Caretakers often describe their birds as inscrutable creatures that behave in completely unfamiliar and unpredictable ways. People don't realize that many of their birds' behaviors are the direct result of the environments they provide and the pattern of interactions they have with their birds. A different problem is a general resistance to the idea of training animals. To some people, training carries the connotation of forcing an animal to succumb to the will of their human captors. They believe parrots should be taught as little as possible so they remain "natural." On the contrary, parrots' tendency to learn is as natural as their tendency to eat and sleep. Learning enables parrots to adapt to life in captivity and in the wild. It also is the mechanism through which we can provide enrichment activities to our birds to improve what might otherwise be a stultifying life in captivity. Concerns about force are immediately dispelled when people learn the teaching technology of applied behavior analysis, which facilitates positive-first learning solutions.

The focus of applied behavior analysis is on the environmental elements that account for behavior. By changing what we do and the environments we provide, we can facilitate behaviors more suited to life in captivity and reduce problem behaviors. This is the way to protect captive parrots from lives locked in cages, multiple homes and eventual homelessness. To make the most of every teaching/learning opportunity, clients need to know how behaviors are learned, how to functionally analyze behavior, how to teach new behaviors, and how to reduce problem behaviors with effective, non-forceful behavior intervention plans. As veterinarians often are the first and only professionals parrot caretakers turn to for help, this information is critical to providing the gold standard of veterinary care and support to companion parrots.

THE ABCs OF BEHAVIOR

Behavior doesn't randomly spurt out of a behaving organism from some internal fount, nor is it performed in a vacuum or broadcast into a void. On the contrary, behavior has function. The function of any particular behavior is related to the environmental stimuli that precede and follow it, called antecedents and consequences. Antecedents are those events or conditions that immediately precede a behavior, which set the occasion for the behavior to occur. Not all preceding events or conditions are functionally related antecedents, just those specifically related to the ensuing behavior. For example consider three common parrot behaviors - screaming, stepping up and biting. Below are examples

of antecedents that may be functionally related to these behaviors in many situations:

When I leave the bird room, then the bird screams. When I offer an open hand, then the bird steps up. When I pet the bird, then the bird bites.

In these examples, leaving the bird room, offering an open hand and petting are all antecedents that are functionally related to the specific behaviors that immediately follow them (eg, screaming, stepping up, biting). Antecedents signal to each individual which behavior to exhibit in any given circumstance. Without the relationship between antecedents and behavior, humans would indeed behave willy-nilly, tossing out behaviors without rhyme or reason; or we may just sit there doing nothing at all.

In day-to-day conversation, the word "consequence" often is used to mean something punitive, as in, "Suffer the consequences!" In behavior analysis, consequences are those events or conditions that affect the future rate of the behaviors they immediately follow. Consequences are outcomes produced by an individual's behavior and provide environmental feedback about whether the behavior just performed should be repeated or modified in the future, when similar circumstances (antecedents) next arise. Of course, consequences don't always come from people. For example, when a new fledgling bumps against a branch when it first takes flight, it will quickly adjust the angle of its wings. No behavior emitted goes without some consequence in return, and all learners actively sift through the feedback to discover how to make behavior "work." We can add the following consequences to our examples of bird behavior from the previous section:

When I leave the bird's room, if the bird screams, then I return.

When I offer an open hand, if the bird steps up, then I praise it.

When I pet the bird, if the bird bites me, then I remove my hand.

Behaviors that produce valued consequences (such as our return to the bird room, praise and the removal of an unwanted hand) tend to be repeated or increased. Behaviors that result in consequences of no value or negative value tend to be modified, decreased or abandoned. In this way, individuals learn to operate on their environment to produce certain outcomes. Skinner called this process "operant" conditioning to emphasize the learning process in which the learner is an *active participant*. (This is in contrast to respondent or Pavlovian conditioning in which the animal is a passive participant, responding reflexively to eliciting stimuli.)

As can be seen in the examples above, consequences also strengthen the antecedent-behavior relationship.

For example, if stepping up consistently produces something of value to your bird, offering your hand will become a strong antecedent for stepping up, as it signals the availability of a valued consequence.

These three terms, *antecedent, behavior* and *consequence*, comprise the ABCs of behavior. Skinner called this three-term contingency the smallest meaningful unit of analysis. In other words, no behavior can be understood in isolation of its related antecedents and consequences. Focusing on our birds' behavior alone has no meaning because their behaviors are not performed in the absence of antecedents and consequences.

FUNCTIONAL ASSESSMENT/ANALYSIS

The process of hypothesizing the functionally related antecedent, behavior and consequence is called functional assessment. It is an important tool for understanding problem behaviors and for devising specific plans to teach new behaviors. With functional analysis, caretakers can determine exactly what leads to and maintains specific parrot behaviors by systematically making changes and evaluating the effect on behavior. Finally, caretakers can design new antecedents and/or consequences to facilitate successful behaviors — their own and their birds'. When caretakers consider behavior in light of this behavior-analytic approach, the causes of problem behaviors and workable solutions often become very clear. Functional assessment and analysis reduce the likelihood that caretakers will resort to unverifiable, hypothetical constructs to explain their parrots' behavior, which may lead them further astray from practical solutions.

There are six basic steps to conducting a functional assessment/analysis:

Step 1: Operationally define the target behavior. A target behavior is the response you want to maintain, increase or decrease. To operationally define the target behavior, describe it in clear, observable terms. Ask: What does the bird actually *do*?

Step 2: Identify the antecedents that set the occasion for the target behavior. Ask: What event or condition immediately precedes or "leads" the bird to exhibit this behavior? Step 3: Identify the consequence that immediately follows the target behavior. Ask: What happens immediately after the behavior is exhibited? What do *you* do or how does the environment respond?

Step 4: Predict the probable future behavior that most likely will occur as a result of the current consequence. Ask: Will the behavior likely be repeated, increased or decreased?

Step 5: Devise and implement a new antecedent and/or consequence to facilitate a different behavior. Ask: What can we do instead?

Step 6: Evaluate the outcome, reanalyze and adjust the teaching program as needed. Ask: Was the desired outcome achieved?

Below are three examples of functional assessments for one very common problem, a bird that refuses to step up from the top of his cage:

Functional Assessment #1: Parrot Refuses to Step Up from Top of Cage

Antecedent: Caretaker says, "Up!" and offers hand to bird on top of cage.

Behavior: Bird performs evasive maneuvers running around the cage top.

Consequence: Caretaker gives up chasing bird and walks away.

Prediction: Bird will continue to run away from his caretaker's hand in the future to avoid being removed from cage top.

Many people ascribe to hypothetical constructs to explain such "misbehavior." One pervasive theory repeated in many popular parrot magazines is that birds are asserting dominance over their caretakers by refusing to step up from the tops of their cages and are vying for control of the human-parrot flock. Caretakers are told that to solve this problem, they need to increase their rank in the eyes of their birds and disallow them from making any important decisions about what they do and when, and never allow their birds higher than the caretaker's heart level. Alternatively, a functional assessment, which adheres to describing the observable relationships between antecedents, behaviors and consequences, suggests a more plausible hypothesis, as described below:

Functional Assessment #2: Bird Willingly Steps Up When Requested

Antecedent: Caretaker says, "Up!" and offers hand to bird on top of cage.

Behavior: Bird steps up.

Consequence: Bird is returned to cage.

Prediction: Bird will step up less in the future to avoid being returned to the cage.

This functional assessment suggests that this bird has learned to run away from the offered hand simply to avoid being locked in its cage. It seems an intelligent choice from the bird's point of view, given the consequences of complying with the request. Unlike the construct explanation, this behavior-analytic explanation meets the scientific criterion of a good hypothesis:

- 1. We can test it by changing the consequence and see if the behavior changes;
- 2. it is as simple as possible, but no simpler;

- 3. it allows us to predict future events; and,
- 4. it is useful, as it implies workable, positive alternatives. For example, most parrots would be very responsive to stepping up from their cage tops if they valued the consequence for doing so. A few moments of attention before being returned to the cage and a treasured food treat after entering the cage are usually all it takes.

Of course, human behavior also is a function of its consequences. Below is a functional assessment of the caretaker's behavior whose bird refuses to step up:

Functional Assessment #3: Caretaker Leaves Bird in Cage

Antecedent: Bird is playing on cage top.

Behavior: Caretaker says, "Up!" and offers hand to bird on top of cage.

Consequence: Bird runs away.

Prediction: Caretaker asks bird to step up less often to avoid refusal.

Chances are, in the long run, this caretaker either will leave his bird in its cage more and/or become more forceful when retrieving the bird. As a result, many birds escalate their initial refusal to biting. All this caging, force and refusal are unnecessary when a simple positive strategy like offering a food treat or a few minutes of uninterrupted attention before being returned to the cage can solve the problem of birds refusing to step up from their cage tops.

Before considering how to change a behavior, caretakers should conduct a functional assessment to determine the function the behavior likely serves for the parrot. The question is not, "Why is the bird behaving this way?" but rather, "What valued consequences result from performing the behavior for this particular bird in this situation?" By changing antecedents and consequences, we change target behaviors. As antecedents and consequences most often are stimuli or conditions we control, changing our birds' behavior always is the direct result of first changing our own behavior.

INCREASING AND MAINTAINING BEHAVIOR

When you think about it, consequences influence behavior in one of two basic ways: Consequences function to maintain/increase the frequency of a behavior or they function to eliminate/decrease the frequency of a behavior. In this section, we are concerned with consequences that function to increase behavior, called reinforcers, and with the process of delivering reinforcers, called reinforcement.

The relationship between behavior and reinforcers is clear, as we see the effect of this principle all around us. When we fasten our seat belts and the buzzer stops, we learn to fasten our seat belts more often to stop the buzzer; when the cat sits in front of the door and we let it out, the cat learns to sit at the door more often to be let out; when the parrot steps up and we take it out of its cage, the parrot learns to step up more often to be removed from its cage.

Characteristics of Effective Reinforcement

Less well considered are the characteristics of effective reinforcement, the most important of which are clear contingency, close contiguity and attention to individual differences. Contingency refers to establishing the dependency between a behavior and its reinforcing consequence. Some people refer to it as "Grandma's Law," which states, "If this is your behavior, then this is your consequence." Thus, reinforcement is the process of delivering a reinforcer contingent upon the performance of a particular behavior. Consistency is important to establishing clear contingency between a behavior and a reinforcer.

Contingency also is clearer when reinforcers are delivered with close contiguity, the second characteristic of effective reinforcement. Contiguity refers to immediacy; that is, the shorter the interval of time between the behavior and the reinforcer, the more effective it will be in increasing the future rate of that behavior. Lattal demonstrated the importance of contiguity in an interesting study with pigeons.¹⁹ In an effort to teach a pigeon to peck a disk, Lattal arranged to deliver a food pellet each time the pigeon moved toward the disk. However, he purposely delayed the delivery of the pellet for just 10 seconds after the target behavior was exhibited. After 40 days of 1-hour training sessions, the pigeon never learned to peck the disk. Subsequently, when the delay between the behavior and the reinforcer was reduced to 1 second, the bird learned to peck the disk in less than 20 minutes.

Reinforcers also are highly individual. Some people are not reinforced by the cessation of the car buzzer and so do not increase the behavior of buckling their seat belt; some cats are not reinforced by going outside, thus, they do not sit by the door; and some parrots are not reinforced by coming out of their cages, preferring instead to drive away the caretaker with a serious bite. Reinforcers are not what we think "should" increase the frequency of a particular behavior; rather, reinforcers are those consequences that actually do increase the frequency of a particular behavior they contingently follow. The only way to know for sure which consequences will be reinforcing for any particular bird is to try them and then observe the future frequency of the behavior.

Developing New Reinforcers

Some consequences such as food, water and warmth are inherently reinforcing to all animals from the moment they are born. These consequences are called unconditional reinforcers (also called unconditioned or primary reinforcers); they are unconditional in the sense that they are not dependent on prior experience (learning), but they do require certain conditions or "establishing operations" to function as reinforcers, eg, hunger, thirst and cold. Surely these unconditional reinforcers are part of nature's clever plan to kick-start behavior at birth for survival.

As soon as an animal starts to interact with its environment, learning begins, and many different consequences become reinforcing by being paired with existing reinforcers. These learned reinforcers are called conditional reinforcers (also called conditioned or secondary reinforcers); they are conditional in the sense that their reinforcing properties are acquired and maintained by being paired with existing reinforcers. Praise, petting and toys are examples of conditional reinforcers for many companion parrots and have become reinforcing though association with food or other valued stimuli.

The more reinforcers an individual parrot has, the more tools we have to influence its behavior, as novelty and variety are essential to effective reinforcement.³⁰ New reinforcers can be conditioned throughout the lives of all animals, and caretakers can make use of this process by pairing existing reinforcers with new stimuli to build a rich pool of reinforcers with which to teach and enrich their parrots' lives. Providing a constant supply of new treats, toys and activities allows our birds to sample new stimuli that may prove to be reinforcing.

Caretakers often complain that they have no way to teach their bird desirable behaviors because the bird has no reinforcers. Of course if that were the case, their bird would have no behavior. It sometimes takes sharp powers of observation to notice what reinforces a particular bird's behavior. Subtle outcomes like being set down or returned to the cage, or a caretaker's retreat, are often conditional reinforcers for poorly socialized birds. We can use even these reinforcers to increase their adaptive behavior, and condition more positive ones by association. For example, to teach a fearful bird to remain calm in our presence, we might start by withdrawing ourselves from its cage for a few seconds contingent on quiet, still behavior. If our removal functions as a reinforcer, we will see calm behavior increase over several repetitions. Again, if our removal functions as a reinforcer, saying "Good!" at the same moment we retreat will result in the word "good" acquiring reinforcing properties for this bird. Eventually, we can advance one

small step at a time, reinforcing calm behavior with the word "good."

Positive and Negative Reinforcement

Admittedly, distinguishing two types of reinforcement with the terms "positive" and "negative" is at best esoteric and at worst utterly confusing. It is tempting just to avert the discussion, define reinforcement precisely and leave it at that. The distinction is pursued here because these terms are so commonly misunderstood and misused, and because positive reinforcement is the preferred strategy for changing behavior, as explained below.

Foremost, reinforcement is reinforcement. That is, regardless of type, positive or negative, reinforcement results in an overall increase in the behavior it follows when next the occasion (antecedent) is set for the behavior to be performed. A positive reinforcer is something that an individual behaves in a particular way to produce (+, add to its environment). It is gaining the reinforcer that functions to increase the behavior with positive reinforcement. Alternatively, a negative reinforcer is something that an individual behaves in a particular way to remove (-, subtract from its environment). It is the removal or escape from the reinforcer that functions to increase behavior with negative reinforcement. The example of increasing a bird's calm behavior contingent upon the caretaker's withdrawal is an example of negative reinforcement, functionally analyzed below:

Antecedent: Caretaker approaches cage.

Behavior: Bird flails.

Consequence: Caretaker remains near cage.

Antecedent: Caretaker remains near cage.

Behavior: Bird stops flailing for an instant.

Consequence: Caretaker steps back 5 paces from cage.

Prediction: Perching calmly will increase to remove care-

taker from cage.

Below are additional examples of positive and negative reinforcement to make this distinction clear. Notice two things:

- 1. In all cases, the target behavior is increased or maintained as these examples all describe reinforcement;
- 2. With negative reinforcement, an aversive stimulus has to be present in the environment in the first place in order to increase behavior by its removal.

Examples of Positive and Negative Reinforcement #1:

Background: Beaker is a parrot that lunges at Grace's hand every time she puts her hand in or near Beaker's cage. Grace has decided to teach (increase) Beaker's behavior of perching on the branch farthest from the food cups so she can replenish them without Beaker's lunging.

Positive reinforcement solution:

Antecedent: Grace says, "Perch!" Behavior: Beaker perches.

Consequence: Grace puts food and the food bowl in cage. Prediction: Beaker will go to the perch more often to

add (+) the food to the environment.

Negative reinforcement solution:

Antecedent: Grace herds Beaker to a particular perch in his cage with a stick.

Behavior: Beaker perches.

Consequence: Grace puts down stick.

Prediction: Beaker will go to the perch more to remove

(-) the stick from the environment.

Examples of Positive and Negative Reinforcement #2:

Background: Of course, Grace also has a problem getting Beaker to step up from inside the cage without lunging.

Positive reinforcement solution:

Antecedent: Grace offers her hand.

Behavior: Beaker steps up.

Consequence: Grace praises Beaker enthusiastically and

sets Beaker on top of the cage.

Prediction: Beaker will step up more to result in Grace's

attention and cage-top location.

Negative reinforcement solution:

Antecedent: Grace holds a towel in one hand while offering her free hand.

onering her free hand.

Behavior: Beaker steps up on free hand. Consequence: Grace sets down towel.

Prediction: Beaker will step up more to result in the

removal of the towel.

As can be seen with these examples, a condition of negative reinforcement is the presence of an aversive stimulus in order for the animal to have something to work to escape. Indeed, another name for negative reinforcement is escape/avoidance learning. Research over decades with many different species of animals has shown that procedures that rely on aversive stimuli, such as negative reinforcement and punishment, tend to be associated with negative behavioral side effects. As you read the common types of side effects, consider how well they describe the behavior of many unfortunate parrots in captivity:

- 1. escape/avoidance behavior,
- 2. aggressive behavior,
- 3. response suppression, and,
- 4. fear of people or things in the environment in which the aversive stimuli are presented.²

The fact that these four general side effects are common descriptions of captive parrots suggests that many birds

experience their environments as negatively reinforcing or outright punishing. Caretakers are encouraged to be analytical about the approaches they employ when interacting with their birds, so that they can deliberately decrease their use of aversive procedures. Positive reinforcement occasions none of this "aversive fallout," clearly making it the preferred behavior change strategy.³⁰

SHAPING NEW BEHAVIOR

So far, we have discussed using positive reinforcement for maintaining or increasing the frequency of behaviors that a bird already performs. Shaping, also called Differential Reinforcement of Successive Approximations, is a procedure to teach new behaviors. To shape a new target behavior, start by contingently reinforcing the response already exhibited by the bird that most closely resembles (approximates) the target behavior. Once mastered (ie, performed without hesitation), reinforcement then is withheld for that behavior. Withholding reinforcement for a previously reinforced behavior is called extinction. Extinction results in an initial increase in responding and effort, which offers natural variability in the way the behavior is offered. Careful observation of this variability allows us to "catch" the next closer approximation with reinforcement. This process of ignoring one behavior (the mastered approximation) and subsequently reinforcing another behavior (the next closer approximation) is called differential reinforcement of successive approximations. Differential reinforcement of successive approximations is continued until the final target behavior is displayed and reinforced.

Many new behaviors required of successful companion parrots can be simply shaped and different dimensions of existing behaviors can be shaped, too. For example, proximity to a feared person or object can be increased; duration staying on a play gym or under a shower can be increased; and latency in responding to the requests "step up" or "off there" can be reduced. With shaping, an endless number and variety of adaptive behaviors can be taught and problem behaviors solved, all with positive reinforcement, thus avoiding the negative side effects that occasion more forceful or coercive methods.

Here's an example of the approximations that can be differentially reinforced to teach a parrot to play with foot toys:

- 1. Look at toy;
- 2. move toward toy;
- 3. touch toy with beak;
- 4. pick up toy with beak;
- 5. hold toy with foot;
- 6. hold toy with foot and manipulate with beak;
- 7. hold toy with foot and manipulate with beak for longer durations;

Table 3.1.1 Intermittent Schedules of Reinforcement

	Fixed (set)	Variable (on average)
Ratio (number)	FR - reinforcement occurs after every "nth" response. FR 3 means that every third response will be reinforced.	VR - the number or responses required before reinforcement varies unpredictably around some average. VR 3 means the number or responses required will average around 3 but will vary.
Interval (time)	FI - reinforcement occurs after a fixed period of time elapses. FI 6" reinforcement will occur after 6 seconds elapse.	VI - the period of time that must elapse before a response is reinforced varies unpredictably around some average. In a VI 10" sched- ule, the average period required before the next response is reinforced is 10".

8. repeat with other toys until the behavior is generalized to all toys.

Unfortunately, negative behaviors can unwittingly be shaped as well. We inadvertently teach our birds to bite harder, scream louder and chase faster through the subtle mechanism of shaping. For better or worse, shaping is endlessly applicable to teaching our birds, limited only by our imagination and our commitment to practicing its use.

SCHEDULES OF REINFORCEMENT

Schedules of reinforcement are the rules we follow to determine when a particular instance of the target response will be reinforced out of the many responses that occur. Several so-called simple schedules are relevant here, as research demonstrates that different ratios of "behavior-to-reinforcement" result in remarkably different, but extremely predictable, patterns of behavior.

A continuous reinforcement schedule (CRF) is one in which each and every occurrence of the target behavior is reinforced. With CRF, the ratio of "behavior-to-reinforcement" is 1:1. Generally speaking, continuous reinforcement is the best reinforcement schedule to use with our birds, especially when the goal is to teach a new behavior or increase the rate of an existing behavior. OCRF is the clearest way of communicating exactly what behavior we want to see again. Research also has demonstrated that individuals behave in proportion to the reinforcement available for a given response. There is little doubt that the more you positively reinforce your bird's desirable behavior, the more frequently your bird will exhibit desirable behavior. We get what we reinforce.

On the other end of the spectrum is a schedule called extinction (EXT), discussed previously as it applies to shaping. With an extinction schedule, no instances of the behavior are reinforced, ie, the ratio of behavior-to-reinforcement is 1:0. As the name suggests, when the particular reinforcer that maintains a behavior is withheld, the rate of that behavior will predictably decrease

to prereinforcement levels. When human attention is the reinforcer maintaining a particular behavior, extinction is synonymous with ignoring, ie, we withdraw attention. Using extinction for the purpose of decreasing an unwanted behavior is not a simple procedure to properly implement. There is much to learn about the correct use of ignoring, which is briefly discussed in a subsequent section.

Somewhere between continuous reinforcement (1:1) and extinction (1:0) is another category of simple schedules of reinforcement known as intermittent reinforcement schedules. With intermittent schedules, only some (as opposed to all or none) of the target behaviors are reinforced. There are two basic dimensions along which intermittent schedules can be arranged: The first dimension regards what is being counted, either frequency of responses (called ratio schedules) or time elapsed (called interval schedules). The second dimension along which intermittent schedules can be arranged regards the predictability of reinforcement, either fixed or variable. With fixed schedules, the ratio (frequency of responses) or interval (length of time) that must occur for reinforcement to be delivered is predetermined and unchanging, ie, it remains the same throughout the program. With variable intermittent schedules, reinforcement fluctuates around a preset average and the learner never knows how many responses, or how long they must wait, for each reinforcer.

Crossing the two dimensions of intermittent reinforcement schedules results in four basic types of intermittent schedules of reinforcement: Fixed ratio (FR), variable ratio (VR), fixed interval (FI) and variable interval (VI). Numbers follow these acronyms to indicate the exact value of the unit of measure (Table 3.1.1). For example, FR 3 means every third response will be reinforced; VR 3 means the number of responses required for reinforcement will vary unpredictably around an average of every third response. An FI 6" means 6 seconds must elapse between the first reinforced response and the next. In a VI 10" schedule, the average period required before the next response is reinforced is 10 seconds.

Intermittent schedules of any kind are known to cause more persistent behavior than continuous schedules under conditions of extinction or very lean reinforcement. For example, many birds try to clamber out of their cages when the door is opened. Every once in a while they make it to the top of the cage. This intermittent reinforcement maintains their persistent effort to "escape" every time the door is opened.

The now classic analogy of the different rates of putting coins in machines observed with a coke machine vs. slot machines is a sound demonstration of the effects of dif-

ferent schedules of reinforcement: With the continuous reinforcement provided by the typical coke machine, most of us do not keep putting money in the slot if nothing comes out. Yet, many people continue to drop coins into slot machines with a very lean schedule of reinforcement. All things considered, our birds benefit most from our ability to "catch them being good" at as high a rate as possible and reinforcing them for it. One important benefit of this approach is that people who deliver dense schedules of reinforcement are more likely to become valued reinforcers themselves.

OBSERVATIONAL LEARNING

Observational learning describes the process of learning by observing the experience of another individual. As described in Chance,⁷ it was not until the 1960s that research on observational learning really took off after initial results with monkeys were reported.³² Since that time, research has demonstrated observational learning takes place with many different species including cats,¹⁴ octopi,¹⁰ bats,¹¹ children and adults.^{16,17}

Irene Pepperberg's work with Alex, the African grey parrot, suggests the effectiveness of observational learning.²⁴ Her work also confirms that observational learning has enormous relevance to increasing adaptive behaviors with parrots that display limited companion repertoires or seriously maladaptive behaviors.

BEHAVIORAL MOMENTUM

Nevin hypothesized that the physics principle of momentum is a good metaphor for behavior.22 He asserts that compliance to demanding or undesirable tasks can be increased by first requesting a series of easy or high-probability behaviors. He calls this procedure behavioral momentum. Behavioral momentum appears to be an effective positive strategy for increasing parrots' compliance to requests they initially balk at doing. For example, one author observed master trainer Phung Luu using this approach with a kea (Kea nestor) learning the husbandry behavior of entering a crate. Having a known negative history with crates (learned during the initial transport to the zoo), the kea ignored the cue to crate several times. Rather than forcing the bird into the crate or accepting that it wouldn't enter the crate, the trainer cued bird to several different perches in rapid succession, something the kea did without hesitation. Once the kea built up behavioral momentum by complying with the easy cues, the trainer asked it to crate at which point the bird actually leaped into the crate where a jackpot of food reinforcers was delivered. Caretakers can use the same procedure to build behavioral momentum with fun, easy behaviors before asking their birds to do something they are less than willing to do. Behavioral momentum is a

positive and effective solution to overcoming behavioral resistance, much preferred over force.

Decreasing Behaviors

Scientifically speaking, punishment is the process by which a consequence decreases the behavior it follows and the consequence itself is called a punisher. As you can see, this simple, functional definition is quite different from common use, which often has more to do with venting anger than actual behavior change. Just like reinforcement, the effect of punishment depends on contingency and contiguity between the behavior and the consequence, as well as the schedule with which the punisher is delivered. Also, just like reinforcement, punishment is a very individual matter. A consequence that is punishing to one bird may not be punishing to the next bird. As always, the function of a consequence can be demonstrated only by observing the future rate of the behavior. If the behavior doesn't decrease over time, the procedure is not punishment.

There also is a distinction between positive (+) and negative (-) punishment. Positive punishment is the process of adding an aversive stimulus to the environment to decrease behavior; negative punishment is the process of removing something of value (ie, a reinforcer) from the environment to decrease behavior. Negative punishment includes relatively mild behavior-decreasing techniques such as extinction and time out from positive reinforcement, both of which are further discussed below.

Unfortunately, positive punishment is all too commonly applied to birds. To reduce unwanted behaviors, people rely on what they know, their "cultural knowledge," which is learned over a lifetime of personal experience with punishment. For lack of alternative information and skills, people often force their birds out of cages in towels, squirt them with water to move them off unapproved perches, and cover their cages to stop them from screaming. They are unaware or skeptical that positive reinforcement solutions are readily available to influence these behaviors.

NEGATIVE SIDE EFFECTS OF PUNISHMENT

As with negative reinforcement, people must be made aware of the predictable side effects occasioned by punishment. These devastating side effects are most likely to result from positive punishment procedures in environments with little opportunity for positive reinforcement. The negative fallout of all aversive strategies is important enough to repeat here:

- 1. escape/avoidance behavior,
- 2. aggressive behavior,

- 3. response suppression, and,
- 4. fear of people or things in the environment in which the aversive stimuli are presented.

Notice that one of the problems with punishment is *not* that it doesn't work. Punishment works to decrease behavior when executed correctly. This fact results in perhaps the most detrimental side effect of punishment — whenever punishment works to decrease an unwanted behavior, the person delivering the punishment is reinforced for using it. Therefore, s/he is more likely to use punishment in the future. This is not only disconcerting, it explains at least one reason punishment is so pervasive in our society, punishment often is reinforcing to the punisher.

DIFFERENTIAL REINFORCEMENT OF INCOMPATIBLE/ALTERNATIVE BEHAVIORS

Fortunately, there are effective alternatives to punishment for decreasing unwanted behaviors, which make use of differential reinforcement. Differential reinforcement first was introduced in the section on shaping, where continuous reinforcement was combined with extinction to advance from one approximation to the next closer approximation of the target behavior. In this section, two differential reinforcement strategies to decrease an unwanted behavior in favor of a desirable alternative are discussed.

With differential reinforcement of an incompatible behavior (DRI), we reinforce a behavior that is incompatible or mutually exclusive with the unwanted behavior, which we ignore. For example, if continuous screaming is targeted for reduction, we can reinforce talking because the two behaviors cannot occur at the same time. If biting people is targeted for reduction, we can reinforce chewing a foot toy because chewing a toy and biting a person are incompatible. DRI allows us to decrease the frequency of the undesirable behavior by increasing the frequency of an incompatible behavior with positive reinforcement. In this way, we take a positive reinforcement approach to decreasing undesirable bird behaviors.

Differential reinforcement of alternative behavior (DRA) is another way to indirectly decrease an unwanted behavior using positive reinforcement. With DRA, the behavior that is reinforced is not necessarily incompatible with the unwanted behavior, but is a more acceptable alternative. For example, a bird that bites to get you to remove your hand instead can be reinforced for a vocalization to make its protests known. Differential reinforcement is a highly effective approach to decreasing unwanted behavior without negative side effects and with all the benefits that positive reinforcement affords.

FUNCTIONAL MISBEHAVIOR

The example of a bird biting its caretaker's hand to result in the caretaker removing her hand from the cage brings up an interesting point: Problem behavior is often a misguided attempt by our birds to communicate a need and/or to get desired reinforcers such as our attention. For example, birds sometime display more raucous vocalizations and increased nippiness communicating that they are tired and ready for sleep. If we teach our birds more acceptable ways to communicate with us, we can decrease their undesirable behavior. This strategy has been validated in several studies with children who were self-injurious, aggressive to others and otherwise disruptive.5 The problem behaviors the children exhibited served a valid communication function as evidenced by the significant decrease in the problem behaviors after the children learned more acceptable alternatives to gain objects, activities and attention.

With this hypothesis in mind, Alberto and Troutman¹ developed three criteria for selecting incompatible and alternative behaviors for DRI and DRA strategies that can be applied to solving behavior problems with our birds:

- 1. Always first analyze the inappropriate behavior to determine if it serves an important function for the bird. If it does, then a replacement behavior should be found that serves that function, but in a more appropriate way.
- 2. The alternative behavior should give the bird the same amount or more reinforcement than the unwanted behavior or it will just revert back to the inappropriate behavior in the long run.
- 3. DRI and DRA strategies work best if the incompatible or alternative behavior already is something the bird knows how to do. In this way, the effort the bird expends can be on replacing an unwanted behavior with a desirable behavior, rather than learning something new.

EXTINCTION

Extinction as it relates to shaping and differential reinforcement of alternative behavior already has been discussed, but it also can be used as a procedure to decrease an unwanted behavior by *permanently* withholding the reinforcement that has maintained it in the past. When human attention is the reinforcer maintaining a behavior, extinction is in effect when the behavior is ignored. Ignoring an unwanted behavior sounds easy enough, however, it actually is one of the most difficult techniques to use effectively.

First, many problem behaviors just cannot be ignored, such as extreme biting, screaming or chewing on woodwork. Second, extinction initially produces a reliable but temporary increase in both frequency and intensity of the unwanted behavior during the beginning stages of the procedure, called an extinction burst. Extinction bursts give new meaning to the phrase, "It's going to get a lot worse before it gets any better." Therefore, when considering using extinction, the critical issue is not whether you can ignore current levels of the behavior, but whether you can ignore significantly escalated levels of the behavior until it finally begins to decrease. Extinction is a relatively slow process and people often inadvertently reinforce unwanted behaviors at these escalated intensities, resulting in worse problems than before they began extinction.

Another challenge using extinction is that we are not always in control of the source of reinforcement that maintains unwanted behaviors. Parrots can derive reinforcement from the feeling they get when they bite our skin and from the reaction of other birds, pets or children in the environment; even an echo in a particular room can reinforce screaming. In these cases, where "bootleg" reinforcement is available to the bird, our efforts to pay no attention to the behavior will have no effect.

Finally, even after a behavior is successfully extinguished, we can count on its sudden reappearance over time. If we prepare caretakers for this "spontaneous recovery," they will more likely reinstitute extinction immediately rather than conclude the initial procedure failed. The good news is that with each reapplication of extinction the behavior is less likely to reappear in the future. Nonetheless, for these reasons, our best strategy for reducing unwanted behavior is differential reinforcement, ie, the combination of extinction of the unwanted behavior and reinforcement of a more adaptive behavior alternative. A sound axiom to guide caretakers in their choice of managing difficult behavior is, "Replace rather than eliminate." By following this rule, we teach the bird what to do instead of solely what not to do, we maintain a higher level of reinforcement and we preserve the function for the bird that was served by the original unwanted behavior.

TIME OUT FROM POSITIVE REINFORCEMENT

Time out from positive reinforcement (TO) is another negative punishment procedure used to decrease unwanted behavior. With TO, behavior is decreased by *temporarily* removing access to desired reinforcers. For example, birds can be taught to leave shirt buttons alone by setting the bird down for a few seconds contingent on the bird moving toward or touching a button. If being with the caretaker is reinforcing, removal from the caretaker will decrease the biting behavior given good delivery of the consequence (ie, contingency and contiguity).

A functional analysis of this program might look like this:

Antecedent: Caretaker is holding bird. Behavior: Bird puts beak on button.

Consequence: Caretaker removes bird to the nearby counter for several seconds.

Prediction: Bird will bite button less to stay with caretaker.

The most common way people fall short with this strategy is by not really removing access to reinforcement at all.

For example, consider the following analysis:

Antecedent: Caretaker is busy preparing dinner.

Behavior: Bird flies to newly reupholstered couch.

Consequence: Caretaker gets bird and walks down the hall, up the stairs, steps over the sleeping dog, passes the ringing phone, passes through the door of the bird room and returns bird to its cage.

Prediction: Bird will fly to newly reupholstered couch to get more time with the caretaker on the way to a distant cage.

At that point, the bird hardly could be aware of the contingency between the misbehavior and the consequence meant to reduce it.

Three additional ways TO is commonly used ineffectively is when:

- 1. birds are removed from reinforcing activities for too long,
- 2. birds are not given another chance to behave appropriately soon after the "infraction," and,
- the caretaker adds reinforcing emotional reactions including brusque movements, strained voices and angry faces.

The effectiveness of TO is greatly increased by following these suggestions:

- 1. Ensure clear contingency and contiguity by selecting a nearby TO location.
- 2. Keep TO short, no more than a few minutes or the bird likely will forget the connection between his behavior and the consequence.
- After a short TO, bring the bird right back to the "scene of the crime" to earn reinforcement for doing it right.
- Let TO do all the work for you. There is no need for other consequences or histrionics, which likely will reinforce the unwanted behavior.

Although TO is a punishment procedure, there is some evidence with children that suggests it can be used without producing the negative side effects of positive punishment.²⁵ In this sense, well-executed TO is a relatively

mild strategy for reducing negative behavior. Even so, antecedent arrangements and positive reinforcement strategies should always be tried first before using any other strategy. If strategies such as extinction or TO are used, special attention should be paid to arranging and reinforcing positive behaviors at a high rate to maintain a positive total environment.

Conclusion

Were it not for parrots' extraordinary ability to adapt on an individual level, one might conclude that at the species level they are genetically ill equipped for the captive environment. Indeed, this may well prove to be the case for some species of parrots. Their high-decibel shrieking, ratchet beaking, food flinging, exclusive bonding, wood remodeling and long-distance flying ways make them demanding animals to care for in our homes. Ensuring parrots' success as companions will require an increased awareness of their species tendencies to set the behavioral context, and a sound working knowledge of how animals learn in order to teach them behaviors well adapted to our homes.

For years, the pervasive approach with companion parrots has been little more than a reflection of cultural beliefs about behavior. The application of scientific information has been scarce. Based on these beliefs, many people assume that behavior is caused by invisible forces originating inside the bird rather than the perpetual interaction between the individual and the environment. For example, one commonly advanced theory is that parrots are driven by a desire for dominance. This is not a benign theory, as it predisposes people to interpret behavior as a struggle for position in some supposed hierarchy and, therefore, to advocate management practices designed for caretakers to win the struggle. Such practices often are forceful and coercive, relying heavily on negative reinforcement and positive punishment, both of which are defined in part by the presence of aversive stimuli.

As a result of this dominance-drive theory, caretakers have been endlessly instructed how to take charge of their birds' behavior, issue commands and establish their superior rank. They've been encouraged to establish control by prying their bird's toes off perches, threatening their birds with towels and ignoring their bird's bites of protest. One of the most disturbing aspects of this dogma is the repeated use of an analogy to sound parenting practice so described: "You wouldn't allow a small child to decide whether or not to take a bath, now would you?" No, we would not; however, the method of choice to facilitate children's bathing would not be to pry, threaten

or ignore cries of protest to get them into the tub. The first step in solving behavior problems is to identify the stimuli in the environment that set the occasion for and reinforces resistance to a reasonable request. The next step is to create an environment that sets the occasion for and reinforces adaptive, cooperative behaviors.

A common criticism voiced by advocates of negative reinforcement and punishment is that positive reinforcement results in increased permissiveness. On the contrary, the skills we want our captive parrots to exhibit do not have to change with this urgent call to change the strategies we use to teach them. For example, with positive reinforcement, parrots can quickly and easily be taught to step up from *all* perching areas; with differential reinforcement of an alternative behavior, parrots can be taught to voice their displeasure rather than bite; and with shaping, parrots can be taught to play independently for a reasonable duration rather than scream incessantly for attention.

Over the course of decades researching and teaching about positive reinforcement, we have heard many unfounded trepidations. Countless times caretakers have asked if teaching with positive reinforcement solutions diminishes intrinsic motivation, results in reward addictions, suppresses the root causes of behavior while addressing mere symptoms, exchanges one symptom for another, promotes bribery, works only with intelligent learners, works only with simple behaviors, requires massive amounts of treats and takes too much work. We are confident to report that given the extensive experimental research base, combined with decades of successful application in schools, zoos and other settings, it is clear that positive reinforcement increases our teaching efficacy in myriad ways and that these concerns are unfounded. And, we are heartened to observe among the parrot-owning public that more and more people are questioning the drawbacks and limitations of using punishment.

Foremost among the many benefits of positive-first teaching is that parrots are taught what *to do* rather than *not do*, and they are empowered to operate on their environment in ways that result in competence and self-reliance. These benefits are especially important in light of the extensive research on learned helplessness, a class of behaviors that results from having little effect on one's own outcomes when repeatedly exposed to aversive events.²⁰ Not only does learned helplessness result in a loss of motivation to improve one's condition when improvement is possible, it is also associated with deficits in learning, performance, and emotional problems. As this research has been replicated with cockroaches,⁴ dogs, cats, monkeys, children and adults,^{20,23} we

have every reason to believe that these effects also are common among parrots.

Finally, applied behavior analysis not only empowers parrots but caretakers as well. Caretakers learn that behavior is functionally related to environmental antecedents and consequences, not some immutable force within. They know where to look to affect behavior directly with positive-first solutions, one behavior at a time, and they understand that to change their birds' behavior, they must change what they do. With a beginning knowledge of the principles of learning and behavior, caretakers also are better able to make reasoned, informed decisions about alternative, less positive

approaches, as needed.

Veterinarians often are in the position of being the first and most credible authority parrot owners turn to for guidance on the behavior of their birds. We could do no better than to turn to the dual sciences of ethology and applied behavior analysis to lead us into a new era of understanding and skill with behavior. In this way, realistic expectations for companion parrots will emerge, as will the commitment to apply scientifically validated, positive-first behavior management strategies. Veterinarians who are knowledgeable about species-level behavior and individual learning will dramatically change the future of companion parrots and their caretakers.

Concepts in Behavior: Section II

Early Psittacine Behavior and Development

LIZ WILSON, CVT, PHOEBE GREENE LINDEN, BA, MA; TERESA L. LIGHTFOOT, BS, DVM, Dipl ABVP-Avian

Ethologists have yet to map out the stages of development for psittacine birds. As a consequence, the information about companion psittacine behavior is predominantly anecdotal and experiential. The wide variation in maturation rates between species as well as between individuals within species, as exemplified in Table 3.2.1, further complicates this issue. As a general rule, the smaller the species, the faster an individual of that species will mature. For example, most cockatiels (*Nymphicus hollandicus*) are sexually mature by 6 months of age, whereas the average 6-month-old hyacinth macaw (*Anodorbynchus hyacinthinus*) has not

yet developed the physical coordination to consistently walk without stumbling.

Generally speaking, small species like budgerigars (*Melopsittacus undulatus*) and cockatiels fledge around 3 to 4 weeks, wean around 6 to 11 weeks and enter puberty at 4 to 6 months. Medium-sized birds (*Psittacus erithacus* and *Amazona* sp.) fledge at 10 to 12 weeks, wean around 12 to 16 weeks and enter puberty at 3 to 4 years of age. Larger psittacines such as *Ara* spp. fledge at about 12 to 15 weeks, wean around 16 to 20 weeks and enter puberty at about 4 to 5 years. Table 3.2.1 presents more detailed information regarding representative species.

Table 3.2.1 | Stages of Development

Species	Fledge (weeks)	Wean (weeks)	Puberty Onset	Sexual Maturity (years)	Geriatric** (years)	Life Span ⁴⁷ (years)
Budgerigar (Melopsitticus undulatus)	3-4	6-7	4-6 months	1	6-12	18
Cockatiels (Nymphicus hollandicus)	3-6	7-11	4-7 months	1	12-18+	32
Sun conure (Aratinga solstitialis)	6-7	8-9	9-18 months	2	18-25	25
Green-cheeked conure (Pyrrhura molinae molinae)	4-6	6-12	9-18 months	2	12-15	25
Peach-faced lovebird (Agapornis roseicollis)	3-6	7-11	7-8 months	1	10-15	12
Yellow-naped Amazon (Amazona ochrocephala auropalliata)	11-13	15-18	4-6 years	7	35-45	
Blue-fronted Amazon (Amazona aestiva)	10-12	12-16	3-5 years	6	25-35	80
Congo grey (Psittacus erithacus)	10-12	12-16	3-5 years	6	20-25	50
Eclectus parrot (Eclectus roratus)	10-11	14-16	3-5 years	6	15-20	20
Galah (rose-breasted cockatoo) (Eolophus roseicapillus)	8-10	11-18	1-2 years	4	18-20	20
Umbrella cockatoo (Cacatua alba)	10-12	12-18	3-4 years	8	20?	
Moluccan cockatoo (Cacatua moluccensis)	12-15	16-25	3-5 years	10	25?	
Yellow-collared macaw (Ara auricollis)	9-10	10-12	1-2 years	4-5	22-27	
Blue and gold macaw (Ara ararauna)	10-12	14-22	4-6 years	8	30-40	50
Green-winged macaw (Ara chloroptera)	12-15	16-35	5-7 years	10-11	35-45	

^{**}True onset of "geriatric" in psittacines is subjective and requires several generations of captive-bred individuals of each species to determine.

Behavior Development and Changes

The larger parrots are generally sexually mature by 3 to 5 years of age. This slow rate of maturation often confuses those who assume that the behaviors displayed in this prolonged babyhood will be permanent rather than transient. For instance, a 2-year-old scarlet macaw (*Ara macao*) is not yet an adult and remnants of youthful behaviors exist. This scarlet macaw can be expected to undergo significant behavioral changes in the future.

As a consequence, some owners are startled and upset at the behaviors displayed as their parrots mature. Those caregivers who are unprepared for avian adulthood routinely complain to veterinarians and behavior consultants that they "want their sweet baby back." The concept of neoteny is powerfully appealing to humans. However, the reality is that parrots continue to grow, mature and change. Psittacine behavior is readily influenced by positive interactions, so caregivers need not lament passing babyhood, but instead embrace life-long learning.

THE NEONATE

Parrots are altricial and are unable to thermoregulate, even in those species that are born with down feathers. Baby parrots are considered neonates from hatching until their eyes open, and during that time their physical needs are simple but absolutely critical: a warm environment and warm food (Fig 3.2.1).¹⁵

Feeding

Many breeders feed their babies on a rigid schedule of every 1 to 4 hours, depending on their ages.²⁴ Waking baby birds to feed them or forcing hungry babies to wait for food until the next scheduled feeding is needlessly stressful for young birds. The optimal feeding schedule is sensitive to the bird's needs, including their rapid increases in weight and the concurrent increase in the volume of food required at each feeding.

Young budgerigars and cockatiels have been documented to solicit feeding with typical baby cries only upon the entrance into the nest box of a parent bird. Occasionally a nestling will cry to solicit feeding from a sibling. The only other vocalizations made are the hissing sound (made by cockatiels even at a young age) at the presence of an intruder in the nest box. Extrapolating this to captive bred nestling parrots would indicate that healthy young psittacine hatchlings should not be prone to indiscriminate or long-lasting crying binges.

Concern with the prevention of sour-crop has promoted the axiom that the crop should be completely empty

Fig 3.2.1 | Despite its blindness, this Moluccan cockatoo hatchling is still exquisitely sensitive to its environment. At this age, temperature is everything, both in environment and food.

prior to the next feeding. Several pitfalls are inherent if this guideline is followed. Liquid food that is fed tends to stretch the crop, and a small pendulous area of crop may retain liquid food for a prolonged period. Waiting for this material to empty produces a hungry baby and creates both emotional and physical stunting. (Ed. Note: Retention of a desiccated portion of the hand-feeding formula may indicate a poorly formulated product, improper temperature of the formula when fed, or prolonged crop-emptying related to illness.) Observation of parent-fed babies demonstrates the normal state of marked crop distention.

Chronically whining baby parrots (especially within the cockatoo family) may be related to prolonged hunger. Breeders who no longer adhere to the rigid scheduled feeding style report neonates that sleep soundly for consecutive hours and awaken eager to eat. Rather than forcing babies to adhere to schedules tailored to human convenience, feeding babies on demand is best for proper physical and emotional growth (Ed. Note: Recent research on African Greys (Psittacus erithacus) and Pionus spp., showed that many babies from parents fed a seed-based diet had some degree of osteomalacia radiographically. Figs 3.2.2a-b demonstrate an advanced case of bony deformation in a ring-necked parakeet. In addition to physical malformations in severe cases of osteomalacia, chronic pain may be present in subclinical cases. Chronic pain at a young age may contribute to excessive crying and potentially to future behavioral problems. See Chapter 5, Calcium Metabolism for further discussion and references.)

Touch

Psittacines wild-caught as adults and not socialized to humans may be adverse to touch. However, naturally

Fig 3.2.2a | An extreme example of osteomalacia from a malnourished diet.

Fig 3.2.2b | The radiograph of the bird in Fig 3.2.2a. Such birds are in pain based on similar problems in species that show more of a pain response, such as monkeys.

occurring parental touch has been reported in many psittacine species. Aviculturist Katy McElroy collects video nest box documentation of Moluccan cockatoos as they lay, incubate, hatch and nurture a baby to fledging. She and subsequent observers are impressed by the "lavish attention" the parents paid to their baby, continuously preening and touching their offspring all over its body between feedings. In one film, McElroy's parent birds are seen with their single baby; all three birds are asleep in the nest box with the baby tucked under its father's wing, its head laid across his back. Like most animals, parrots are most likely adverse to rough handling, but readily accept appropriate touching, especially when raised to do so from an early age.²⁰

There is an obvious positive reaction to touch, with neonates responding to soft stroking and wing tip massage by pushing their heads into the human hand. Prior to the opening of their eyes, they also will respond to the sound of a familiar step and voice, popping their heads up on wobbly necks. One author (PL) has noted the importance of duplicating the weight of the parent bird's wing when raising babies in incubators, especially when a single chick is housed alone. The baby or babies should be placed into a secure container and covered with towels that rest lightly on the neonates. Soft weight on the back quiets a baby after feeding.

McElroy reports that her video has documented the extreme sensitivity of baby cockatoos to parental and sibling touch. "They sit upright on their bottoms a few hours after hatching and use their feet propped out like stabilizers to keep from tipping over. The slightest touch will cause them to spin around in that direction, using one foot as a pivot as they search for food or a warm body. You rarely see a baby that isn't snuggled up against a sibling or parent. If two blind neonates get acciden-

tally kicked apart when the parents leave the box, they will both stretch their necks out and lurch around in circles until making contact" (K. McElroy, personal communications/e-mail, 2002). The importance of physical contact for neonates should not be ignored. The keeping of multiple chicks together increases normal physical stimulation. Incubator-hatched birds should have touch massage incorporated into their daily care.

Light

Prior to their eyes opening, neonatal parrots are responsive to light. Biologically designed to begin life in the darkness of a tree cavity, baby parrots react adversely to strong light by flinching, hiding or trembling. As a consequence, the popular practice of keeping babies in glass aquariums under fluorescent lights not only is potentially detrimental to the developing eyes of neonates, but also might cause psychological distress. ¹⁵ Because their eyes need time to develop slowly in a darkened cavity, many aviculturists supply neonates with a darkened container in which to grow and develop. Handraised psittacine babies actually gain weight faster when kept in the dark. ²⁵

THE NESTLING

After the neonatal psittacine's eyes open, the baby is categorized as a nestling. Psittacine birds with recently opened eyes seem to be myopic, which is consistent with most newborn animals. Certainly babies who are confined in a closed container have no need to see across vast distances. If given the opportunity to do so too early in the development process, nestlings will blink, recoil and seek a dark corner. They do, however, move toward and touch objects in close proximity, so boxes can be enriched at this stage to encourage visual development.

Fig 3.2.3a | This African grey baby was raised in a plastic incubator with its physiologic needs met. However, the excessive exposure to light, lack of parental or sibling weight, heat and support, are potentially psychologically devastating. Here the baby is hiding after being frightened by a ringing phone.

Fig 3.2.3b | Baby blue and gold macaws benefit from an enriched cardboard box environment with a covered corner for hiding when needed.

As feathers develop and open, the need for supplemental heat decreases, and young psittacines can be moved out of brooders into unheated containers that allow more movement but still resemble a nest. The limited space has been demonstrated by Nigel Harcourt-Brown to be a critical factor in the prevention of valgus deformities of the legs in neonatal birds. ^{15a} When the babies are fully feathered, they can be housed at room temperature, (72-78° F, 22-26° C), which should be carefully monitored. Various containment systems employ the judicious use of towels to provide darkness, privacy, traction and hiding places that appear to be critical to a stress-free environment. For further comfort and physical and psychological safety, food sources must continue in a dependable manner and the environment must remain secure.

Visual Stimulation

Appropriately stimulating environments are vital to mental development; the use of bright colors and accessible, touchable toys are enrichments that are simple to incorporate into young psittacine environments. Designs on nursery walls and colorful mobiles are examples of visual enrichment for birds at the peri-fledgling stage when they are perching intermittently on the edge of the nest box.

As the baby bird develops increased visual ability and physical mobility, increased opportunities for learning must be provided. Fearless curiosity is characteristic of young animals,⁵ and this characteristic is best utilized in teaching the young bird to competently deal with the world. In addition to the previously noted necessities of warmth, food and security, the neonates' environment needs increasing stimulation in terms of vision, touch, sound and interaction.

Borrowing again from early development of more extensively studied species, it is fair to assume the existence of a window of opportunity for the development of visual recognition, learning and acceptance in psittacines. Therefore, to make the view more interesting, one can hang bright posters and add plants (either real or artificial) to the nursery. People can wear bright colors when working with babies. Colorful towels that cover the containers are simple enrichments. By rotating the towels every couple of days, caretakers can ensure the babies become accustomed to different patterns and colors. In this manner, an early foundation is laid that encourages the birds to be receptive to change.

Baby parrots raised in opaque plastic tubs receive no visual stimulation. Cutting a notch in the side of the tub (melting the edges so they are not sharp) so the babies can see out can counteract this lack of visual stimulation. Organic containers are more natural and stimulating: simple cardboard boxes (which can easily be cut to provide a view and disposed of when soiled) or inexpensive natural-colored baskets. Whatever the environment, caretakers should cover most of the container with towels throughout the day, and cover it completely at night. This provides privacy as well as darkness, should a baby become overstimulated (Fig 3.2.3a). The towel coverings also influence thermoregulation and should be adjusted as needed (Fig 3.2.3b). Both the need to withdraw from stimulation and the need for warmth decrease as the birds continue to develop.27

Most veterinarians use towels to restrain birds. Acclimating a bird to being restrained in a towel will reduce the stress of veterinary visits and aid in grooming at home. Initially, cover the baby with the towel and let

Fig 3.2.4a | Picking a safe color towel and teaching a bird restraint will make veterinary exams and training easier as a bird matures. Here a bird is introduced to a towel.

Fig 3.2.4b | Slowly covering the bird with the towel in a reassuring way.

Fig 3.2.4c | Adding pressure and restraint slowly over time allows grooming and examination or restraint whenever needed in a safe unfrightening way.

it sleep. As the bird nears fledging, it can be carried around in the towel. It can then be introduced to different areas of the house, people, objects, and other pets, using withdrawal into the towel for security. It is likely, as is documented in dogs and cats, that if a bird is not introduced to certain animal species by a certain age, it will have difficulty accepting the presence of this species in the future without fear. The positive and negative results of creating this fearless state need to be considered (See Socialization and Co-parenting Section to follow [Figs 3.2.4a-c]).

Parrots spend large amounts of time with their faces close to their babies. As the babies develop, visual contact—face-to-face and eye-to-eye—soon expands into vocal interactions post feeding, as the babies respond to gentle murmuring of the hand-feeder. Introduction to adult foods during the neonatal period will increase acceptance and prevent the development of food rigidities in the future (Figs 3.2.5a-b).

Tactile Stimulation

Periodically stroking baby birds with warm hands simulates parental attention. One author (PGL) has observed the following regarding toenail sensitivity in baby birds:

"Touch the toenail clipper to the nail while holding the baby securely. Some birds do not flinch at all, while others react with varying degrees of withdrawal. Interestingly, this relative sensitivity is consistent into fledging."

Subsequent training exercises are used to desensitize the tender-footed neonate at an early age, while continuing to increase the amount of reinforcement the less reactive baby receives.

Aural Stimulation

Vocal communication between parents and chicks begins early. Hand-feeders are encouraged to talk to the babies in their care, accustoming them to human voices and language. Varieties of other types of sounds also are healthy and useful. The positive aspects of music have been proven repeatedly with animals as well as people.

Reactive Attachment Disorder

Reactive attachment disorder involves children 5 years old or younger. This condition was known in previous centuries as orphanage baby syndrome and is better known in the current lay literature as failure to thrive. Defined as "a disturbance of social interaction and relatedness", this condition is associated with "grossly pathological care, with persistent disregard for a child's basic emotional needs for comfort, stimulation and affection, as well as repeated changes of the primary caregiver that prevent the formation of appropriate bonds." This severe absence

Fig 3.2.5a | Shown are examples of the most valuable types of moist foods to be offered to baby birds to teach variety. Starting at mid left going clockwise: organic acorn squash, lettuce, beets and beet tops, broccoli, carrots, yams (sweet potatoes) and butternut squash.

Fig 3.2.5b | An example of the proper kinds, amounts and types of organic dry foods to teach a baby bird to accept, for macawsized birds on the left and Amazon-sized birds on the right. These bowls show the amount of food offered to a pair of the respective birds mentioned. The limiting of seeds and nuts is vital; these are offered only to breeding birds until the babies are weaned. Then the nuts and seeds should be stopped altogether for the babies and suspended until the next breeding period for the parents.

of care can result in serious psychological and *physical* problems in children, such as stunted growth, the inability to socialize appropriately and increased potential for self-destructive behaviors later in life.¹³

Currently, many captive-bred, hand-fed parrots do not know how to play, accept appropriate touching, interact or even how to eat a variety of foods. Perhaps as a result of improper or incomplete early development, increasing numbers of parrots engage in feather destruction and even self-mutilation as adults. Increasing numbers of young domestically bred and hand-fed parrots seem unable to form a healthy relationship with humans. The authors wonder if these increasing problems are related to psittacines being raised in an assembly-line fashion in a cold, clinical nursery. If this is the case, the production-raising of psittacine birds is not the best technique for producing an emotionally and physically stable companion animal. Happily, the industry seems to be turning away from production techniques, as evidenced by the important work being done in large facilities such as the University of California-Davis and Texas A&M.26

The dangers of creating "failure to thrive" are lessened to an extent by raising neonates together rather than in individual enclosures. When aviculturists have substantiated the health of their babies (see Chapter 21, Preventive Medicine and Screening), the young of certain species may be housed together; in these mixed-species settings animation and interaction increase. Early work on raising psittacines in mixed-species groups yielded such good results—youngsters that seek touching, sleep readily, play with and seem curious about others—that the practice is widely accepted by many breeders today.

Socialization and Co-parenting

Socialization is a process by which an individual forms an attachment to other species.3 Time frames for socialization in birds are not established as they have been for dogs and cats. The hand-feeding of psittacine chicks certainly provides exposure to humans. Conversely, provision of all the natural elements outlined in this chapter-feeding, warmth and tactile, visual and vocal stimulation—can be difficult for the human caregiver to provide. Ongoing studies at the University of California-Davis with co-parenting have shown great promise. Pairs of orange-winged Amazons (Amazona amazonica) were raised by their parents through fledging, with university students interacting with the young in the nest box for brief but regular periods of time. The study is ongoing, but preliminary results show that limited handling by humans for short periods, several times a week, may produce offspring that are socialized to humans, but benefit from all the inherent advantages of parent-raised birds. Extreme caution should be exercised in the selection of parents and young for this protocol to ensure that parental infanticide, abandonment or abuse does not occur.

THE FLEDGLING

Prior to fledging, babies show increasing interest in the world outside their enclosure. A partial covering of towels will enable the babies to see out of their container or to retreat and hide. As they get braver, they will spend more time looking out of the container and less time in concealment. There is often a great deal of wing flapping that happens inside the nest as babies start building up their pectoral muscles.

As their foot and leg strength develops with exercise, low perches should be added to the inside of the container. In this way, babies can perch when they wish and also stand flat-footed when they prefer.

As their distance vision improves, objects that stimulate vision can be added to the nursery walls. When possible, a view of the outdoors should be provided. Visual acuity continues to increases as the bird spends more time observing objects and movement outside of the nest box. For instance, immediately after opening their eyes, Eclectus nestlings will track food as it comes toward their eyes, but remain largely unresponsive to noiseless activities farther away. As the weeks progress, these birds track movements at greater distances. Just prior to fledging, birds can be seen scanning the horizon, (e.g., tracking an airplane's progress in the distant sky), and then quickly adapting their vision to objects presented at close range. Play behavior increases with developing visual acuity. McElroy describes a 6-week-old Moluccan chick that plays with a parent's molted feather in the nest box, flapping her wings wildly and rolling around as if she had another bird as a playmate.

A fledgling is a young bird that is learning to fly. In nature, fledging happens prior to weaning, which is logical when one realizes that a parrot baby must develop the physical strength and dexterity to learn controlled flight before it follows its parents to various and distant food sources. Only then is it sufficiently developed to achieve the complex manual dexterity necessary to eat on its own. Flight competence therefore precedes weaning in psittacine birds.

In the past, aviculturists automatically clipped the wings of baby parrots at their first attempt at flight. The popular belief was that the psittacines would not miss flight if never allowed to fly. However, in the last few years it has been recognized that fledging can make a marked difference in a bird's physical and emotional development, even when the wings are later clipped.¹⁷ Fledging is a normal part of psittacine development and allowing this stage to progress naturally makes the weaning process much easier.16 An excellent example of this phenomenon is the African grey parrot. African grey babies formerly were perceived as being awkward and prone to falling. Actually, this species is amazingly adept at flight and readily learns to maneuver in mid-air if given adequate opportunity. After all, wild babies that fall frequently surely could not survive. The African grey's reputation for clumsiness has more to do with early wing clipping than with any inherent lack of coordination.

The fledgling psittacine is a creature obsessed. Though still food-dependent, the fledgling often loses interest in eating. Flight becomes all-consuming and weight loss

Fig 3.2.6 A blue and gold fledgling displays a partial wing clip that slows flight but does not curtail it. Graduated clipping done over a period of several days is recommended over a severe clip that ends flight abruptly.

is normal at this stage, as the youngsters lose baby fat and slim down to a more streamlined, aerodynamic figure. Inexperienced hand-feeders often are confused by this phase if they assume that the lack of interest in food indicates that fledglings are starting to wean. This is not the case. The process of weaning doesn't begin for another week or more after fledging, so caretakers should continue to hand-feed appropriate foods at every possible opportunity. Although requiring a dedicated area to avoid serious damage to the bird or one's environment, fledging confers significant developmental advantages. The young psittacine's coordination, muscular structure and social skills increase as the fledgling learns to interact with a wider variety of flock members once flight is achieved.

Should a new owner wish trimmed wings on his young parrot, a gradual wing clip is preferable to the abrupt curtailment of flight. Instead of a drastic clipping of flight feathers, graduated clips, several days apart, should be performed, gradually limiting flight (Fig 3.2.6).

THE WEANLING

"To wean" is defined as "to accustom to take food other than by nursing" and second as "to detach from a source of dependence."²² A weaned parrot is capable of survival with little or no guidance in procuring adequate nutrition. Weaned wild birds, therefore, find and supply themselves with a variety of nutritious foods in sufficient quantity.¹⁴ The best weaning process for psittacine companions allows eating skills to develop gradually over a period of several weeks. Unfortunately, many pet stores and breeders consider a baby parrot "weaned" as soon as it shows interest in eating on its own; which is a regrettable and potentially fatal misconception. The weaning process is a gradual process wherein a baby parrot learns where, what and how to eat. There are

Fig 3.2.7 | A young female eclectus enjoys a meal of squash and the novelty of new foods. Just as in human children, messy eating and experimentation are part of the process of learning to accept and enjoy foods of various textures, shapes and tastes.

numerous motor skills necessary to accomplish this, and these take time to develop.

Psittacine parents assist in the weaning process by holding food in their beak and feet for their babies. Human caretakers can assist parrot weanlings by finger-feeding warm, wet food. Ideal foods for this technique include chunks of cooked squash, carrots or yams and mango. Weaning pellets, or the type of formulated diet that is to be fed when the bird is weaned, can be soaked and offered in this same manner (Fig 3.2.7). All foods are warmed and moistened in hot water or fruit juice. The temperature range is critical for maximum palatability and digestion. Foods should be warmed to $104 - 105^{\circ}$ F (38-38.5° C). Candy thermometers work well for this and are available in any kitchen supply store.

Using a camera in the nest box of a pair of wild-caught Moluccan cockatoos (*Cacatua moluccensis*), the process of raising a youngster was videotaped for 11 months. Although the baby was noted to be typically noisy while being fed, it was never noted to cry for food or to get the parent's attention (K. McElroy, personal communications, 2002).

Conversely, Harrison's observation of a trio of black cockatoos in Australia depicted the parents and their young flying from tree to tree. While the parents located and ingested food, they ignored the crying of their accompanying youngster for 30 minutes. The youngster finally chose and ingested food on its own. This was obviously the final stage of weaning, as the baby was not easily differentiated from the adults.¹⁰

A possible explanation for variations of parental participation in feeding young after fledging may be reflected by the environmental conditions of the species.

Dissimilar environments might produce substantial disparities in the urgency of achieving food-independence. Development is faster in parrots from dry regions than in those from rain forests. This is because the period in which food is most abundant is shorter in an arid environment like the Australian hinterland than on an Indonesian island where there is considerably more tree cover.²⁵ Differences in parental post-fledging feeding have been noted among cockatiels, lovebirds, budgerigars and *Eclectus* sp. (Kavanau 1987).

Reasons for these differences are still speculative. Therefore, we must astutely analyze the circumstances associated with crying in the baby bird in order to respond appropriately.

VOCALIZATION

During a specific developmental period, young psittacine birds develop a loud, repetitive, plaintive call, which would, in the wild, signal parent birds to locate those fledglings. Key developmental events collide at this point: young fledglings learn to fly, navigate, land, come and follow and practice independent eating skills. Therefore, conscientious caregivers are challenged to carefully observe crying fledglings to determine what the cries signal. Does this young psittacine need comfort, exercise or food?

If comfort is needed, the bird should be held only until it settles down. If the bird needs exercise, playtime can be initiated wherein the fledgling is encouraged to try new physical skills such as flapping or climbing. If the bird is hungry, it should be fed a moderate amount of food and then shown how to forage to find accessible foods.

While some parent birds might actually let their babies cry in order to have them practice making a verifiable retrieval signal, this cry has a function separate from the cry of a hungry youngster. In no case should young fledglings be ignored or allowed to go hungry. Teaching a bird to whisper and to hum can be immediately rewarding and contribute to acceptable vocalization for years to come.

Selling Unweaned Parrots and Force-weaning

Avian veterinarians see a multitude of potentially serious medical problems when unweaned parrots are sold to inexperienced caregivers. Some cases of aspiration pneumonia and crop burns are treatable but some are fatal, and most are preventable through ethical breeding and sales practices. Many feel strongly that the practice of selling unweaned birds should be made illegal, as it is with puppies and kittens. However, should that happen, the fear is that baby parrots will be "force-weaned" in an effort to expedite the weaning process.

Force-weaning entails withdrawing hand-feeding when parrots are still begging for it, based on the belief that hunger will *force* the babies to start eating on their own. A multitude of behavioral problems may be associated with forced or stressful weaning. ¹⁶

Baby parrots that are force-weaned often later become high strung, hyper-responsive to stimuli, prone to stress and rigid in their eating habits. When eating skills are not firmly in place and readily practiced, underlying undesirable behaviors manifest. Force-weaned African greys, for instance, seem much more prone to developing phobic behaviors later in life than do abundantly weaned African greys.²⁸ Cockatoos that are force-weaned often become chronic whiners, which may contribute to cockatoo prolapse syndrome. The large macaws, probably not truly "food-independent" in the wild until they are at least 6 to 9 months old, often are the victims of force-weaning. When macaws are force-weaned, they generally get into patterns of obsessive food begging, often with repetitive wing flicking and a typical macaw begging sound well into adulthood.4 Birds that are weaned prematurely will exhibit chronic begging behaviors. It is common for them to flap one wing and bob their heads for food while crouched down.1 In contrast, properly weaned birds will run to a food bowl, investigate its contents, and select a morsel and consume it, albeit wastefully. The aberrant behaviors of force-weaned birds are assumed to result from deprivation during a critical period of their development.

THE JUVENILE OR PREADOLESCENT

The hallmark of this period of psittacine development is often the bird's refusal to cooperate. Increased independence and increased athleticism both necessitate training and learning that is critical to the future development of the parrot and cohabitation with humans. Most of the medium and large species of parrots listed in the "Pets for Sale" section in local newspapers will be between 8 and 24 months of age (Fig 3.2.8). When properly reinforced for desirable behaviors, this need not be an overly stressful time for bird or owner (see Chapter 3, Behavior, Section I, The Natural Science of Behavior).

Juvenile Molt

Juvenile parrots often experience a heavy and uncomfortable molt that may make them irritable when touched. Molting parrots can be testy at any age, so one must assume that they are uncomfortable. Owners should be cautious when petting their birds, as it is easy for human fingers to accidentally inflict pain. Gentle stroking with a feather or toothbrush is suggested at these times, as this may decrease the bird's discomfort. Frequent bathing also can help during this period; either self-bathing,

Fig 3.2.8 A juvenile Moluccan cockatoo in full display. Juveniles can be a challenge, but less so if clear, consistent controls and limits are established for their behavior.

enclosure in a bathroom with the shower running to create high humidity, or exposure to actual, warm rainfall. Increased humidity will soften the keratin sheaths of pinfeathers and enable them to open more easily.

Bathing Skills

Bathing skills are critical for good feather and skin health, and a thoroughly soaked parrot is inspired to healthy feather grooming. Many parrots are rain forest species that evolved in environments where annual rainfall is measured in feet, not inches. Even those from arid regions often are found within flying distance of water pools or rain-drenched microhabitats where bathing opportunities abound. With artificial heat and air conditioning, human environments are seriously dry, so periodic soakings are needed to counteract these conditions. Bathing skills are important for young parrots to learn, and caretakers must be patient and creative in discovering an individual bird's preferred bathing technique. Some parrots prefer pool bathing in a shallow dish, and some leaf bathe in wet kale, romaine and chard. Others prefer rain bathing via a hand-held sprayer, the human's shower stall, a garden hose or natural rain on warm summer days. It is important for caretakers not to frighten a young parrot with the introduction to bathing. This may create fears that can be difficult to overcome.11,12 Additionally, parrots who bathe or shower with vigor also are adept at exercise because the two vital functions reinforce each other. (Ed. Note: Some believe that blow-drying should be vehemently discouraged, as this can negate the positive effects of bathing by drying out feathers and skin. Others disagree, believing that blow-drying is acceptable if it is tolerated by the bird and carefully regulated to prevent burns or overbeating.)

Exercise

Exercise is important to parrots of all ages, and it is

Fig 3.2.9 | Under close supervision, wing-trimmed fledgling macaws play in juniper bush while showering. Exuberant exercise is critical to physical and psychological health for psittacines as well as functionally decreasing problems in the captive environment. Tired parrots tend to be quiet parrots.

Fig 3.2.10 | Prey species like psittacines need the choice to be visible or not, so providing hiding places can greatly decrease stress for any age of psittacine. With his softened face feathers, this fledgling yellow-naped Amazon displays the comfort level allowed by providing such choices.

especially important for juveniles. Parrots evolved to fly many miles each day in the wild, and this inherent need for exercise is critical for success in the captive environment. Flying and/or flapping exercises are a daily necessity, and caretakers should encourage these activities in their parrots. Exercise also is enhanced by the use of movable perches and the provisions of branches, rather than the thick, stationary perches (Fig 3.2.9).

Juveniles should be encouraged to chew, shred and otherwise pulverize a variety of destructible toys. Natural branches from non-toxic, non-sprayed trees, complete with bark and leaves, are ideal for parrots, and caretakers should be encouraged to find a constant source of such things as bamboo and willow for their birds.

The Human Environment and the Companion Parrot

Cage Placement

The ideal area in which to place a bird's cage is dependent on the personality of the specific bird. Most parrots enjoy being in the center of human activity, but care should be taken to allow for the instinctive insecurities of a prey animal. Placing a cage against a solid wall provides security, but many parrots enjoy a window view. Cages may be placed partially against a window and partially against a solid wall to provide the advantages of both security and stimulation.

Extroverted parrots that are caged away from human activities often scream excessively. Anxious, skittish parrots may start showing feather-destructive behaviors if

caged in the middle of a high-traffic area, especially if the bird is startled by people appearing without warning.

The height of the cage also is important. Many parrots appear comfortable when allowed to perch at human chest or shoulder level. If caged too low, an insecure parrot can become seriously frightened. If caged too high, headstrong individuals may be more difficult to handle. Hiding places also are important, so parrots are allowed the choice of whether or not to be visible (Fig 3.2.10). Hiding places can include branches wired to the outside of the cage to produce a "thicket-like barrier" (M.S. Athan, personal communications, 2000), a fabric cover over one corner or wooden boxes attached to the side of the cage.

Environmental Enrichment

Because of the psittacine's need to forage and shred, suitable objects are necessary components of the enriched environment. Destructible objects, such as safe branches with leaves and bark intact, paper cups, tongue depressors and cotton-tipped applicators, also can keep parrots quietly and inexpensively absorbed.⁷ One author's own blue and gold macaw hen (*Ara ararauna*) methodically works its way through an old phonebook once or twice a year, spending several weeks of intensive work to render the entire publication into thumbnail-sized pieces. This activity appears to diffuse aggression.²³

Four categories of parrot toys have been described: chew toys, climbing toys, foot toys and puzzle toys. A small number of stimulating toys, rotated on a weekly basis, seems to hold a parrot's interest. One toy from each category might satisfy most parrots' need to play, investigate and destroy, and also leave sufficient room

for the bird to move around its cage. In a very large cage or aviary, toys might be placed randomly about in order to encourage the parrots to use their entire territory.

Foraging

A recent study demonstrates the value of environmental enrichment in psittacine birds.²¹ The use of foods and toys for foraging activities and environmental enrichment is a long-standing tradition in many companion and avicultural situations. Foraging is encouraged when foods are offered in new and challenging ways, such as stuffing an empty tissue box with greens or hiding a food within view but not within reach, eg, inside a puzzle toy. Parrot owners must devise methods to keep their birds occupied, especially during the long hours spent alone.

Toys also are useful as deflectors of aggressive energy, especially with species like Amazons. These birds may interact roughly with their toys, dissipating potentially aggressive energy.

Adequate Sleep

Sleep is another important consideration, especially with a young parrot. The actual sleep requirements and the presence of active (REM) vs. slow-wave sleep have not been determined in various psittacine species. In dogs the "active sleep-quiet sleep," or slow-wave (REM) sleep cycle, is only 20 minutes as compared to 90 minutes in humans. In the absence of controlled data on normal sleep rhythms, extrapolation and observation must be used to tentatively determine a pet bird's sleep requirements. As tropical and neotropical species, most companion parrot species evolved in an environment that provided 12 hours of darkness and daylight, year-round.

As previously mentioned, due to their social nature, parrots often are caged in high-traffic areas. This places them in locations with extended hours of noise and artificial light. When questioned about sleep, owners generally believe that covering the bird initiates sleep. More accurate information would be derived from asking what time the noise ceases and the lighting is extinguished in the evening.²⁹

Rather than declare major rooms off limits past a certain hour to give a parrot more sleep, veterinary ethologist Andrew Leuscher originated the concept of the "sleep cage." A sleep cage is a small, sparsely equipped cage that is kept in a room that is unoccupied by humans at night, and it allows parrots to be put to bed at a reasonable hour. This allows them to get the hours of dark and uninterrupted sleep that they appear to need. Behavioral manifestations of sleep deprivation in parrots include hyperactivity, aggression, excessive screaming (especially after sunset) and feather-destructive behaviors such as plucking.

TRAINING THE YOUNG PSITTACINE

Young parrots need reinforcement for appropriate behavior. Parrots, like other animals, will perform best for positive reinforcement and will soon discard behaviors for which they receive no reinforcement. Without training, parrots do not understand how to be good companions and people do not understand how to be good caregivers.

Activities appropriate for the young bird to learn include physical lessons such as swinging, flapping and climbing. With these athletic adventures, young birds learn to burn their calories in appropriate ways and don't have massive amounts of energy left over at the end of each day for screaming, pacing or hyperactivity. In addition to physical activities, young birds should be encouraged to develop social skills that allow them to take food from human hands, to play with toys with various people, and to step up on either an offered hand or a hand-held perch. Vocal skills also benefit young psittacines who are encouraged to modulate their contact calls with more pleasing and less repetitive, less plaintive vocalizations, such as soft chortling and whistles.

The owner should train the young parrot to accept handling that facilitates life as a successful companion, such as entering and exiting the cage and stepping up and down upon request. Ideally, parrots should be trained to tolerate procedures such as grooming; this can greatly minimize stress but is difficult for most people to accomplish with their pet bird.

Parrots that do not receive rudimentary training are apt to lose their homes for two reasons: (1) caregivers tend to lose interest in "unmanageable" birds; (2) untrained parrots shape their own behaviors into less compatible actions such as screaming and biting.

Parrots should not be making decisions, such as whether or not they wish to go back in their cages or whether or not they wish to get off of the owner's shoulders. Parrots that learn to respond to reasonable requests are those that consistently benefit most from positive reinforcement, and caregivers should be aided in finding positive ways to teach their birds.

It is also important to understand that parrots are independent creatures. While parrots should step on the human hand on command when they exit their cages, the act of compliance with this command should be made a positive experience. For instance, rather than wait until the last possible second to return birds to their cages when owners are stressed and pre-occupied by being late for work, they will have greater success if they choose to re-cage their parrots earlier under more relaxed circumstances. For example, to remove a parrot

from its cage, the owner may approach the cage and ask the bird if it wants to come out. Observation of body language readily answers this question. If the answer is affirmative, the parrot generally moves forward, and/or picks up a foot. If so the owner opens the cage door and uses the "Up" command to which the bird has been trained. A negative response is equally obvious—the bird moves away and/or turns its back. If the response is negative, the interaction is ended. No command has been given, so no control has been lost.⁸

Birds vary in their reaction to food as a motivator for behavior. Most owners cannot and do not wish to withhold food from their birds in order to stimulate foodmotivated behavior. However, some who manipulate delivery of a favorite food report surprisingly good results. Therefore, rewards should be selected for their efficacy in eliciting and reinforcing desired behaviors.²¹

Juvenile Behavior Problems

For detailed analysis of the various problem behaviors seen in companion parrots, refer to Section III of this chapter. Many of the problems seen in older birds have their foundation in mishandling of the youngster.

Inappropriate behaviors become problems when they are inadvertently reinforced, such as the baby that lunges at a stranger, only to be hugged and soothed (and therefore rewarded for aggression) by the owner. Some birds will hold onto their owner, or their cage door, as the owner attempts to return them to their cage. This should be recognized as early defiant behavior and addressed.

SUMMARY

Aviculture undoubtedly will continue to raise psittacine birds destined to become human companions as long as humans demand them. Accordingly, the need continues for examination of psittacine development. Appropriate diets, stimulation, security, regular and consistent sleep, appropriate lighting and sufficient exercise are important for the development of young parrots. Fledging should be part of the optimal psittacine development. Training techniques that enhance success in the human environment include basic handling skills (such as cage entrance and exit competence). When we properly educate ourselves, we can raise young psittacines that have an excellent basis for success in their captive environment.

Concepts in Behavior: Section III

Pubescent and Adult Psittacine Behavior

LIZ WILSON, CVT; TERESA L. LIGHTFOOT, BS, DVM, Dipl ABVP-Avian

The prevalence of captive-raised psittacines as pets and the ensuing problem behaviors have become critical issues for veterinarians as well as aviculturists and parrot owners. Ethological considerations should occupy a large area of future study, concern and advancement.

The terms adolescent and puberty in this chapter are used to identify the period of development during which hormonal changes play an active role in both the initiation of reproductive capacity and associated variations in temperament. Recognition of the role of sexual hormones in psittacine behavior is critical to the interpretation and modification of behavior.

Puberty

As with other psittacine developmental stages, the onset of puberty varies with the species and the individual (see Table 3.2.1 in Section II of this chapter). If erratic behavior is inadvertently rewarded it may continue after the sexual hormonal fluctuations of puberty have subsided.⁹

Owners are often unprepared for the prolonged developmental changes that their pet psittacine will undergo. Clearly established behavioral boundaries will decrease but not eliminate hormone-induced behavior. To aid in establishing rules and guidelines, the types of behavior for which the animal is reinforced must be examined. Pubescent parrots can learn to behave in ways that mitigate obnoxious behaviors, hormonal or not, and should be appropriately reinforced for non-reproductive behaviors if they are meant to be non-reproductive companions.

Increasing sexual hormone levels may lead to the first instances of territoriality and perceived aggression (Fig 3.3.1).¹ In the adolescent parrot, fluctuating hormones add to the inherently high energy level to produce a bird that needs directed, acceptable methods for dissi-

pating this energy. Daily flapping exercise, play with toys and showers consume natural energy and provide learning opportunities with inherent reinforcement. Once through puberty, the adult psittacine may display a more predictable pattern of behavior (Fig 3.3.2).

The Adult Psittacine Companion

In the wild, constant challenges test the parrot's athleticism, ability to avoid predation and to find food. To succeed in such a demanding environment, parrots must be flexible, adaptable and continue to learn. It has been estimated that the average parrot's day is divided thusly: 50% of waking daylight hours spent locating and consuming food; 25% spent interacting with one's mate and/or other flock members; and 25% spent in preening (J. Harris, personal communication, 1996). In contrast, there are few challenging activities in the human habitat. Alone in a cage all day, the monotony is pronounced. Enrichments, especially ones that encourage foraging behavior, will provide appropriate learning and athletic experiences for captive psittacines.

Management issues can significantly contribute to problem behaviors. Inadequate diet or sleep and boredom can all be problematic. Cage size, location and height are also important. Refer to Chapter 2, The Companion Bird, for discussions of these subjects.

TRAINING

Psittacines should be trained to step on and off both the hand and a hand-held perch and to enter and exit their cages on command. They also should be trained to step from one hand to the other, an exercise called "laddering." When training a parrot, it is preferable to work out

Fig 3.3.1 | Sexually hormonal female yellow-naped Amazon parrot that is agitated. Note the erect neck feathers and forward-leaning stance as she defends her position on a cage door.

Fig 3.3.2 | Umbrella cockatoo exhibiting "alert" display. Species and individual variation dictate how a parrot in this "state" should be approached.

of sight of a parrot's perceived territory. Lessons should be short and upbeat, with rewards that are meaningful to the bird. Positive interactions and praise work well for parrots that already like their trainers. Correct responses should be instantly rewarded. The reward will vary with the personality of the individual parrot. It may be praise, desired physical contact such as head scratching, or a food treat (see Section I of this Chapter).

The species most prone to feather destruction and self-mutilation in domestic life often inhabit large flocks in the wild, and these same animals may therefore have evolved extensive interactions within a social order. When social order is ambiguous or absent in the human habitat, high levels of stress may result.²⁷

Color Preferences and Applications

Many birds have preferred colors and other colors that are associated with fear or avoidance. To evaluate an individual bird's color preferences, place the parrot in a confined area with six or seven identical children's colored wooden or plastic blocks or balls. Note the colors the parrot avoids and those with which it plays. Remove the objects in the colors it ignores or avoids. Repeat this test several times to verify the preferences.

The positive colors can be supplied in the form of other items in the parrot's environment. During training, utilize these favorite colors in the selection of clothing, perches and food cups (Fig 3.3.3). This color selection can aid in the acclimation and acceptance of toweling in parrots (see Chapter 6, Maximizing Information from the

Physical Examination). Teaching of toweling to young parrots can include playing "hide and seek" with towels of preferred colors, while gradually increasing the parrot's acceptance of restraint.

EXERCISE AND PLAY

The importance of exercise and play increases with the adolescent parrot and continues to be an important skill throughout psittacine life. Behaviorists have equated the amount of play in which the young engage with a species' general adaptability. Studies of keas (Nestor notabilis) are particularly compelling in this regard.²³ Play behavior is consistently demonstrated in properly raised captive psittacines. According to one biologist, "The question of 'play' in animals is an intriguing one. We use the word to connote activity that has no obvious use in daily life almost a frivolous pastime. In fact, play has an important function for the animals that engage in it, humans included, and particularly for their young. It is a way of developing dexterity and motor coordination, and of discerning the boundaries of social behavior, skills that are critical to success as an adult. Play, as we know from watching our children, is a form of learning."15

Problem Behaviors in Captivity

An understanding of normal psittacine behavior is necessary when attempting to address problem behaviors in captivity (Fig 3.3.4). For example, it is perfectly normal for a parrot to use its beak when climbing, even when climbing onto a human hand. If that hand jerks in

Fig 3.3.3 | This lovebird is well-adapted to toweling by its owner and prefers the color blue.

Fig 3.3.4 | This is a common species threat posture displayed by a nervous green-winged macaw willing to defend against entry into its cage.

anticipation of a "bite," and the parrot doesn't reach its destination, the next time it might try a different (harder, perhaps) grip before it steps. It has been observed that inexpert handling by humans fuels fear in young parrots. Further, psittacines are normally loud, destructive and messy animals. While these behaviors may distress the people who live with them, they are not aberrant.

When one examines a "problem" behavior, the first question to ask is; "What function does the behavior serve?" Behavior has a function, which means that every learning-based animal performs certain behaviors based on what the animal gets as a result of that behavior (see Section I of this chapter).

INAPPROPRIATE BONDS

Some birds are reinforced when they show aggression toward less-favored people. Their actions may be accompanied by screaming, laughing or crying, culminating in a rescue by the favored person. All this vocalization and activity is positive reinforcement.

Owners can work with their parrots to prevent overbonding to one person. A useful technique is Blanchard's handling exercise called the warm potato game. A neutral room is ideal for this purpose. The parrot is passed from person to person with each member interacting positively (ie, praise, petting, treats) with the bird. This handling exercise should be continued for the duration of the parrot's life. To avoid alarming the timid parrot, the socialization process can begin by stepping onto the shoe of a less-favored person (sitting with one leg crossed), then be stepped back to the familiar hand and rewarded. 30

People may inadvertently allow their parrots to form a mate bond with them (Fig 3.3.5). Owners often stroke their companion parrot's back and tail.¹⁸ Breeding

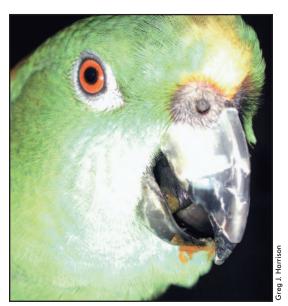

Fig 3.3.5 | This yellow-naped Amazon has been sexually regurgitating its food to the owner, and it has some of this food on its beak.

parrots perform these behaviors during courtship and we therefore assume that companion parrots interpret this type of petting as sexual. Panting and masturbatory behavior often follow such intimate touching. Serious aggression may follow, when the bird attempts to drive all creatures except the perceived mate from its territory. When unable to reach the targets of its attack, this bird may displace its aggression, often in the form of a severe bite, to the perceived mate or even to themselves.

COCKATOO VENT PROLAPSE

This syndrome is extremely common in adult umbrella (*Cacatua alba*) and Moluccan (*Cacatua moluccensis*) cockatoos. Generally, these parrots are strongly bonded to a human. Several veterinarians³⁸ (Van Sant, personal communication, 2002) have made the observation that

Fig 3.3.6 | Prolapsed cloaca on an umbrella cockatoo.

Fig 3.3.7 | Closer look at the prolapsed cloaca in Fig 3.3.6.

Fig 3.3.8 | After prolaspe is reduced, loss of elasticity and dilation of the cloacal lips are evident.

delayed weaning appears related to this phenomenon (see below). Although the etiology is still speculative, several characteristics have been noted in most of these cases. They:

- Are hand-raised individuals of the noted cockatoo species.
- Experienced delayed weaning and/or continued begging for food.
- Are psychologically attached to at least one person. Have a tendency to hold stool in their vent for prolonged periods (ie, overnight) rather than defecating in their cage. This may be exaggerated by potty training these parrots.

Prolonged begging for food causes straining and dilation of the vent. Misplaced sexual attraction to their "human" mate also will cause vent straining and movement. Retention of stool in the vent for prolonged periods stretches and dilates the cloaca. The vent lips in these birds are often distended and flaccid (Figs 3.3.6-3.3.8).

Behavioral modification is difficult for owners to accomplish, since it involves altering the tight bond that they have with their parrot. Behaviors that increase this inappropriate bonding in affected cockatoos include stroking the parrot, especially on the back (ie, petting), feeding the parrot warm foods by hand or mouth, and cuddling the parrot close to the body.

If the parrot perceives the owner as either its parent or its mate, it will continue to strain and the prolapse will likely recur despite surgical correction (see Cloacopexy in Chapter 35, Surgical Resolution of Soft Tissue Disorders). Some veterinarians have found that a total change of environment and human companionship (ie, finding the parrot a new home, either temporarily or permanently) is necessary to correct this problem.

PROLONGED HORMONAL STIMULATION

Captive-bred parrots display sexual behaviors at earlier ages than their tree-ranging counterparts. Eclectus hens (Eclectus roratus), for example, may lay eggs in captivity at 3 years of age. In the wild, eclectus hens generally don't begin to lay until about 6 years of age. 18 Sexually mature companion psittacines are also developing what some avian veterinarians call "hormone toxicity." Instead of going into nesting behavior once a year, circumstances in the human habitat can cause parrots to remain hormonally stimulated indefinitely. In the wild, seasonal triggers, like changes in photoperiod, suitable nesting sites and ample food, initiate nesting behavior. Similar triggers initiate nesting behavior in captivity (Table 3.3.1), but the artificial environment provides not only safety from predation but also confusing signals. Artificial light mimics the long days of summer, and seasonal variations are lacking. The same is true of temperature, as indoor parrots are protected from cyclic change. Food is abundant and some parrots are fed daily rations that provide many times their caloric needs.18

In parrots that become aggressive when in breeding mode, pupillary constriction, filoerection of the nape or

Table 3.3.1 | Foods that Encourage Breeding or Foods to Avoid to Reduce Breeding Behavior

Sweet items	Immature items such as corn, beans and peas Apples Grapes Citrus Bananas
Refined carbohydrates	Pasta Breads and other baked goods

crest feathers, or flexion of the joints of the wing will convey a warning of the parrot's agitation and potential reaction to further approach (Figs 3.3.1, 3.3.2). If these warning signs are not recognized, both physical and emotional damage may occur.⁷ Some companion psittacine species become reproductively active once a year and during the remaining months are not so frenetic.²²

In recent years, sexual hormone manipulation has been attempted with compounds such as chorionic gonadotropin or a GnRH agonist.^b These medications may temporarily ameliorate the problem behaviors of hormonal aggression, as well as physical problems like chronic egg laying (see Chapter 19, Endocrine Considerations and Chapter 9, Therapeutic Agents). However, if the parrot's environment contains triggers for nesting behavior, sexual hormone levels may remain high despite the administration of these medications. Environmental triggers must be eliminated before lasting relief can be found.²⁸

One aviculturist cites the following example of "energy management." He suggests redirecting psittacine energy into survival behaviors instead of reproductive behaviors. In the case of one excessively hormonal female umbrella cockatoo, he randomly modified the heat and light in the parrot room, the amounts and types of food offered, and the bird's perception of safety (by not covering the cage every night). Paper was provided during the day to shred. Within a week, the hen had returned to normal behavior. (G. Wallan, personal communication, 2002).

CHEWING

Chewing is not something that parrots "grow out of," as do puppies. Owners who complain that their psittacine is chewing the wall behind the cage should move the cage, supervise their parrots when out of their cages, and teach their parrots to chew on well-designed toys or other appropriate items. Dried pine cones, natural fresh branches from unsprayed trees such as apple, citrus, melaleuca, Australian pine, ash, beech, and aspen are also ideal. Indeed, bark chewing and eating behaviors have been observed in African greys in Africa.³¹

EXCESSIVE VOCALIZATION

People frequently ask how to "teach their parrots how to be quiet." Parrots are loud animals and they cannot be taught to be otherwise. When lay bird magazines tout a particular species as being "quiet," this does not mean that parrots of that species make no noise; it means they make less noise than the species that are known to be very loud.

Normal noise levels vary from species to species, but generally speaking, parrots tend to vocalize loudly several times a day for 5 to 15 minutes. The large macaws,

Case Study: Excessive Screaming

A 9-year-old male umbrella cockatoo (*Cacatua alba*) was screaming for hours on end and neighbors were beginning to complain.

Through the process of taking a detailed history the following information was discovered. The bird's cage backed up to a half-wall that allowed visibility from all directions and the bird had no hiding place in its cage. The cockatoo was getting only 6 hours of dark, uninterrupted sleep and was eating a high-sugar, low-nutrition diet. The owners also were unknowingly allowing sexual behaviors such as masturbation and had little control over the cockatoo.

The approach to this problem was multifaceted. The owners purchased a sleep cage and began putting the bird to bed at a much earlier hour, enabling 10 hours of sleep. A large towel was positioned over one end of the parrot's cage, allowing the bird to withdraw from sight whenever he wished, and the owners discovered that the bird chose to spend a great deal of time behind the barrier. The diet was adjusted and the owners began having daily lessons to establish better control. Sexual behaviors were curtailed with no punishment or drama. Within a couple of weeks, the screaming had abated tremendously, and 2 years later, the owners (and their neighbors) continued to be very pleased with the decrease in the bird's vocalizations to expected levels.

Amazons and cockatoos normally will produce 15- to 20minute bursts of screams several times per day, especially morning and evening.

Incessant screaming is not normal behavior. Once again, the first step to changing a behavior is to analyze its function: what does the parrot achieve by screaming? Does the screaming parrot yell to get the owner's attention, to obtain food or to alleviate boredom? Many parrots that scream excessively do so to liven up their monotonous existence.⁴³ See Section I of this Chapter for more information on inadvertent reinforcement of excessive screaming.

When taking a behavioral history, ask the owners *what they do* when their bird screams. They may let the parrot out of its cage, pick the parrot up, give it a treat to quiet it or yell at the bird. Unfortunately, all these responses are rewards and reinforce the behavior.

Modifying Screaming Behavior

There are inherent problems with most cases of excessive screaming. First is duration, because the more time

parrots have been reinforced for screaming, the more ingrained is the behavior. It is also essential that all people involved understand that changing screaming behavior requires participation by all the humans in the area. If one person in the environment continues to reward the screaming, the behavior will not change.

The resolution of any behavior problem requires a stepby-step approach (see Section I of this chapter for more information). Circumstances that precede the behavior should be documented. These may include:

- · Time of day
- · Day of the week
- Activity/mood/noise level in the household
- The parrot's body language
- Relation to feeding time

Reactions that accompany or follow the screaming should be recorded (as these may be the inadvertent reinforcers of the behavior).

Owners are instructed to collect but not interpret data for 10 to 14 days. If a pattern is detected, steps can be taken to change what leads up to the behavior and the response to the behavior, therefore changing the behavior itself⁶³ (see Section I of this chapter for an in-depth discussion of this behavioral model).

To successfully decrease excessive screaming, owners must be consistent and patient. If a parrot screams while caretakers are in the room, they can turn their backs and momentarily withdraw their attention. This maneuver is classified as a "time out." The second the racket quiets, they can turn back to the parrot and gently, so as not to reignite a screaming fit, reward with smiles, praise or acceptable food treats. If the screaming begins again, caretakers should turn their backs and leave the room, leaving the parrot alone. They should not return until the parrot has temporarily quieted.

If they are not in the same room when a screaming episode begins, they are to do nothing until the parrot quiets briefly and preferably makes some acceptable type of noise. Then they can reenter the room and reward the parrot for either silence or acceptable vocalizations. Extinguishing excessive screaming will not produce a completely quiet parrot.²⁵

Parrots often scream excessively when company arrives. Owners can take the following preemptive steps: (1) Do not feed the parrot for 4 to 6 hours prior to company arriving; (2) Encourage the parrot to engage in flapping session, followed by a drenching shower. Once accomplished, move them to a sleep cage in a separate room (for more information on sleep cages, see Chapter 2, The Companion Bird); and (3) Give the bird a meal and

some special treats hidden in a difficult-to-get-at toy.

There are exceptions to the rule of ignoring excessive screaming. When the human "flock" reunites, parrots tend to celebrate this occasion with raucous noise. Owners should not ignore the bird in this situation. Instead, they should greet their parrots and spend a couple of minutes interacting with them. Owners should then ignore any noise that happens after a parrot is suitably greeted. A second exception has been termed the "contact call."24 In the wild, a parrot's flock represents the safety and protection of numbers. When other flock members are not visible, for example, when a flock is feeding in the heavy foliage of the rain forest canopy, they may use the contact call. Its function is to make certain they have not become separated from the flock. Companion parrots also do this, and they are simply making certain they are not alone. When contact calls are not answered, they often escalate to a scream. If a scream is required to receive a response, this inadvertently reinforces screaming.

African greys (*Psittacus erithacus erithacus*) have been described as learning human contact calls, such as the ringing of the phone and the beep of a microwave. It is postulated that they mimic these sounds when they are seeking contact with the members of their human flock.²⁶ Cage location also can influence levels of psittacine vocalization.

Without an area in which to hide, vigilance behavior may be displayed as excessive vocalization.

BITING

Unlike excessive noise, biting may not be grounded in instinct. According to observations made of parrots in the wild, the beak is used for eating, preening and social interaction, not as a weapon against other flock members. Wild parrots use complicated body language, feather position and voice to express themselves in situations of conflict with others in their flock. When a confrontation is not quickly resolved, they simply fly away rather than engage in actual combat. 36,37,39

Most captive parrots are caged and have clipped wings, so instinctive responses such as flight are not an option. Hence, biting becomes a common behavior in captivity.

The Functions of Biting

As was previously mentioned, it is critically important to analyze the function of a behavior before appropriate recommendations can be made. A detailed history must be obtained. There are wide varieties of stimuli that motivate a parrot to bite, and these need to be identified and analyzed.

Fear-based Biting

The issue of fear is a critical consideration with a parrot. Psittacines tend to be frightened of novel objects or situations, as their survival in the wild would be enhanced by approaching new things with extreme caution. Owners may not realize this and become impatient with their parrot, increasing rather than dissipating its fear. One needs to look for techniques to gradually desensitize the parrot to fear stimuli.

Biting and Territoriality

Parrots, like most animals, have territorial impulses.³ If a parrot starts to lunge when around any perimeter, it is labeled as "territorial." Caregivers can alter the configuration of that perimeter, preferably with enrichment, decreasing the territorial response. Preferred behaviors should simultaneously be reinforced. Commonly identified perimeters frequently include nest boxes, feeding stations, play gyms, dark places, cage interiors and cage doorways. The territory outside of these locations can be made more enriching than the protected areas. For example, the parrot that balks at leaving its cage can be shown, before the cage exit is requested, that the reward it will get contingent upon removal from the cage is greater than that of solitude.

Case Study: Fear-Based Biting:

Normally sweet and unaggressive, Lily, a 9-month-old African grey (*Psittacus erithacus erithacus*) hen abruptly started biting when her owner's friends tried to handle her. She became especially aggressive with her person's new boyfriend, striking quickly and biting hard.

Lily was biting from fear-based aggression. Frightened by non-flock members, she needed to be better socialized. If not identified and handled properly, a shy parrot like Lily can blossom into a determined fear biter. Lily's person needed to reassure her that she was safe when interacting with others.

Introducing her to other people in neutral territory with patience and sensitivity, the owner taught Lily that new people are fun and interesting. Initially, she expected Lily only to step onto the outsider's hand politely, and then step right back onto her trusted caretaker's hand. Lily's good manners were then lavishly rewarded with smiles and praise. Each time Lily did this successfully, she discovered that positive things happened when she was compliant with new people. As a result, Lily learned to enjoy interactions with non-flock members.

As exemplified by the frequent springtime attacks of small songbirds on substantially larger predators, like raptors, dogs and people, parrots take their territoriality quite seriously. Owners who allow their parrots total freedom in the home unwittingly exacerbate this problem, as the parrots may then defend wider areas from non-favored people.²¹ In extreme cases, parrots assume the entire house as their territory, attacking anyone who enters.

By training parrots to enter and exit the cage on command, caretakers maintain control over the cage space, preventing territorial aggression. This is easily accomplished by teaching parrots that they must step onto the offered hand or hand-held perch if they wish to exit the cage. ¹³ If parrots do wish to come out of the cage, owners should not just open the cage door and walk away, allowing the parrots to exit whenever they choose. Instead, parrots should be taught to politely step onto a perch or the hand prior to exiting the cage. Feeding such a parrot away from the cage makes the effort of getting the parrot out of its cage easier.

Parrots that have a very small living area (cage) may have increased territorial instincts. Setting up a number of other play areas can decrease territorial instinct back to a more normal level.

Case Study: Biting as a Learned Defense

An extremely polite and unflappable 3-year-old male African grey had always been very sweet and easy to handle, so this author (LW) was quite startled when the owner recently complained that the grey had been biting her.

When questioned regarding the circumstances, the owner revealed that the bird was biting only when she was trying to pet him. Upon further questioning, the owner admitted that on each occasion, the bird had pushed her hand away several times before it would bite. This was a clear example of biting as a learned defense. The bird obviously had tried to communicate to the owner that it did not wish to be petted, but the owner did not understand. When the frustrated bird finally resorted to biting, the woman ceased her attempts to fondle it.

In this manner, the owner was very clearly sending the message that nothing short of violence would get her to stop forcing herself on the bird. It was explained to the owner that the parrot had politely refused her attentions and that request should be honored. The domesticated dog is the only animal that is always in the mood to be petted, and a parrot is not, after all, a dog with feathers.

Case Study: Territorial Aggression

Clients complained that their 14-year-old male yellow-naped Amazon (*Amazona ochrocephala auropalliata*) was lunging and biting at family members as they walked by his cage.

The location of cages and playgyms can strongly influence parrot behaviors. In this situation, questioning revealed that the Amazon's cage was in the middle of a high-traffic intersection, on the same wall with doors. The consultant explained that while these social creatures like being in the middle of the action, they can get overstimulated by constant traffic flowing by their cages, as well as being startled repeatedly by the abrupt appearance of humans. Owners need to remember that parrots are prey animals that often react aggressively when frightened. This aggressive behavior was eliminated when the owners relocated the cage out of the middle of the traffic flow over to a far wall where the Amazon could see people coming.

Parrots are often not comfortable with strangers invading their cage space. If interaction with a stranger is to be attempted, the parrot should be removed from the cage first and then introduced to the stranger. When the protected territory is a person to which the bird is strongly bonded, owners must be vigilant to prevent injury to other persons, the bird or themselves (see Mate-bonding).

HEIGHT

No true dominance has been documented in birds as relates to their relative perching height. Ornithologist Jim Murphy commented, "Height does have its advantages, and behaviors can and do change as a result of it. Height alone confers a temporary advantage if there is the determination on the part of the involved individual parrot to exercise that advantage." Parrots that become incorrigible when above eye level are already out of control, and this becomes more obvious with the increased altitude. 46

In some situations, a temporary easement of problems can result simply from raising the people. For example, a footstool placed next to a high play gym can enable shorter people to more easily reach and therefore have better control over a parrot.²⁰ Whether being at an increased height changes a parrot's perception of its status or decreases its perceived vulnerability is still under debate. Regardless of the psychology behind it, most parrot species that are incompletely trained are more compliant on the floor than when perched on top of a tall cage.

SHOULDERING

A potentially dangerous but extremely popular practice is allowing parrots onto people's shoulders. A popular tradition over centuries of parrot ownership, this practice probably did not become especially dangerous until the advent of captive-bred parrots.

It has long been understood by raptor specialists that there is a substantial difference between raptors that have been captured and tamed and those that are domestically raised and socialized to humans. Birds of prey that have been socialized to humans have no fundamental fear of people and they can become extremely dangerous when in nesting season, aggressively attacking people who encroach on their territory (M.J. Stretch, personal communications, 2000). Imprinted hawks may need to be tethered during nesting season to prevent them from attacking people. Due to their potential aggression toward humans, these raptors cannot be released into the wild. The similar reaction seems to occur in captive-bred parrots. Allowing parrots on the shoulder can be particularly hazardous.

Additionally, a psittacine on a human's shoulder easily can reach vulnerable parts of the owner's anatomy (eyes, ears, noses, lips). Facial injuries can be severe and also permanently damage the parrot-human bond. Parrots should not be allowed on a human's shoulder. This is one of the few issues on which all experienced persons involved in parrot behavior agree. 4,10,19,20,40

BEHAVIORAL MODIFICATION FOR BITING

Undesired behaviors often can be avoided by interpretation of psittacine body language. Careful observation is the first step in this process. Once experienced in reading body language, people will find that it is easier to anticipate and avoid a bite.

A parrot most often resorts to biting when other potentials for communication have been exhausted. It then continues to bite because it has been reinforced for doing so. For example, a parrot often will respond to unwanted human attention by raising its foot to fend off the hand, or by pushing the hand away with their beak. Humans will get bitten if they ignore these warnings.

Owners reaching for a parrot while they are on the phone may trigger a biting reaction. Psittacines often behave as if they dislike telephones. From the bird's perspective, the ringing telephone elicits an immediate response. The owner holds the phone to their ear and interacts with it verbally. It is not surprising that parrots act so negatively to this apparatus.

An owner can often prevent a bite by making direct eye contact and putting a hand or finger up as a counterpoint of attention, while quietly but firmly saying something like, "Be good" or "Settle down." Seldom will a parrot break eye contact in order to bite. Other methods of prevention include giving the parrot something on which to place its beak while stepping it onto the hand, or approaching from behind instead of offering the hand from the front.

When a parrot attempts to bite while sitting on a hand or arm, there are two techniques that can be effective. Athan's "Wobble Correction" entails a tiny rotation of the arm or hand.⁵ Davis' "Little Earthquake" involves performing a slight drop of the hand or arm.¹⁰ If used consistently, parrots soon make the connection between biting and losing their balance.

Laddering can be can effective deterrent to biting. This is the exercise described previously in "Training" in this section. The technique is the same, but the handler's facial expression and tone of voice is quiet and firm and the handler is frowning. When the parrot follows the command, the owners tone turns positive, and the bird is then placed on a perch. Laddering works well with many cases of aggression when firmly implemented.

Some owners are not aware that parrots normally use their beaks as hands rather than weapons. Afraid of being bitten, these people often pull away when a bird reaches for them with their beaks. Repetition of this exchange will teach young parrots that if they wish to climb onto a hand they must grab it quickly. At some point the bird may grab the human hand with enough force to cause pain. If this is rewarded with vocalization by the person (such as "OW, BAD BIRD, NO BITE!"), the bird has received positive reinforcement. Instead of verbal reinforcement, a stern look and a quiet, firm, "No" without withdrawing the hand is most effective. Once reprimanded, the parrot can be given a toy with which to play, offering it a healthy outlet for exploration with its beak.

Neurotic Fears or Phobias

According to human psychology, a phobia is defined as "any unfounded or unreasonable dread or fear." It is not unfounded or unreasonable for a prey animal such as a parrot to be afraid of a predator such as a human, and this reaction would be expected in wild psittacines. However, most pet psittacines are acclimated to the human captive environment. When there is no precipitating incident and the parrot is suddenly terrified of people, noises, shadows, or comparable non-threatening

items, the definition of phobic would seem to apply.

There are few situations as frustrating as dealing with the phobic or neurotic parrot. The classic signalment is a high-strung young parrot that suddenly begins reacting to humans as if they are deadly predators. This is especially upsetting when the formerly beloved owner is an object of their terror. The parrot may flail around its cage, screaming and trying to escape when the owner approaches. A "phobic" parrot is not simply afraid of new toys or new people, it also overreacts to noise, movement, and even direct eye-contact from humans. These parrots often break multiple blood feathers, and cause extensive soft tissue damage to their keel and wing tips. 12

Ordinarily, aggressive parrots are not phobic (J. Doss, personal communications, 1997-1998). There has been discussion concerning whether these are two different responses to the same stimulus. If so, insecure parrots that perceive themselves as threatened can become either phobic or aggressive, depending on individual personality type (P. Linden, L. Dicker, personal communications, 1997). Some species are particularly prone to phobic behaviors, including small cockatoos like the rose-breasted (Eolophus roseicapillus), citron-crested (Cacatua sulphurea citrinocristata) and triton (C. s. triton); small Poicephalus (Meyers [P. meyeri] and Senegal parrots [P. senegalus]); African greys (especially the Congo [*Psittacus erithacus erithacus*]); and eclectus parrots (Eclectus roratus). These same species also are predisposed to feather-destructive behaviors.

The etiologies of phobic behavior are unknown. A particular incident may precipitate phobic behavior, but the actual underlying causes may be species-specific tendencies and developmental problems (see Relative

Case Studies: The Non-Phobic Phobic

Care must be taken to accurately diagnose phobics, since they are handled so differently from the more common problem behaviors seen in companion parrots. One author (IW) worked with a "phobic" yellow-naped Amazon (*Amazona ochrocephala auropalliata*) that turned out to have an idiopathic medical problem that predisposed the parrot to falling from the hand because it could not grip properly with its feet. Multiple falls taught the parrot a direct correlation between handling and pain. The result was a dramatic fear response when people approached. Interestingly enough, the Amazon's screaming and flailing was eliminated by the use of the dopamine antagonist, haloperidol^c (D. Kupersmith, personal communications, 1997-1998).

^{*} Products with 3 mg of sodium or more per serving should be avoided in feather picking birds. Restrict foods to recommended yellow fruits and vegetables (G.J. Harrison, personal communication, 2003).

Attachment Disorder in Section II of this chapter). Potential exacerbating events may include physical or psychological trauma such as aggressive capture and restraint techniques. 42 Ethologists agree that aggressive handling or "punishment" is not the only reason that parrots become phobic (A. Luescher, J. Oliva-Purdy, L. Seibert, personal communications, 2003). Often there is no discernible history of abuse.

Rehabilitation of a phobic parrot can be a painfully slow and difficult process. Misinterpretation and mishandling of phobic behavior may increase the severity of the problem.⁴⁴ Various psychotropic drugs may be used in conjunction with behavioral modification to aid in the treatment of phobic parrots. Many of these drugs are also used for parrots with feather destructive behavior. Species specificities seem to exist but much of this information is still anecdotal. One author (TLL) has had rela-

Case Study: Feather Destruction

A 3-year-old male African grey (*Psittacus erithacus erithacus*) was boarded with this author (LW), and on presentation the bird had removed all its contour feathers on its chest, leaving only down.

The impetus for this behavior became obvious when the bird yanked out feathers whenever its wishes were frustrated. When the grey apparently realized that no one would acquiesce to its desires, the motivation for the plucking was removed and the behavior ceased. The bird went home 3 weeks later with a dramatic increase in contour feathers on its chest, and the owners were delighted. However, they renewed their behavior of complying with the bird's wishes whenever it touched a feather, so the bird promptly reduced its feather coat to only down again.

The owners opted to do a consult at this point, and learned how to avoid reinforcing the bird and the behavior ceased once again. There were periodic episodes of plucking over the next few years (such as when the owners purchased a Great Dane puppy), but when the owners did not reward the feather destruction with attention, it ceased after a short period. At this time, the bird is fully feathered.

It is felt that success in a feather picker is that it does not escalate, may cease, or does not mutilate. It has been noted in many cases that during times of stress, which varies from case to case (a storm, a new pet, new people, a new home or changes in the home) the bird will revert at least temporarily to picking (G.J. Harrison, personal communication, 2003). Guaranteeing a cure is seldom fulfilled.

tively good results in with several African greys using a combination of diazepam and fluoxetine, or diazepam and amitriptyline. Conversely, haloperidol has worked in a number of *Cacatua* species, but the same dose caused excessive agitation in a male black-headed caique (*Pionites melanocephalus*), an eclectus (*Eclectus roratus*) female and one eleanora cockatoo (*Cacatua eleanori*) (see Chapter 9, Therapeutic Agents).

Feather Destruction and Self-mutilation

Feather destructive behavior is a condition seen only in, and therefore caused in some manner by, captivity.¹⁷ Species predilections exist, with African greys and cockatoos being over represented. Psychological as well as

physical etiologies contribute to feather-destructive behavior.²⁷

Feather-destructive behavior is a clinical sign, not a disease entity. Nutritional causes, including malnutrition and food, pesticide, dye or preservative sensitivities, and excess salt or sodium may be causative (Table 3.3.2). Environmental factors including low humidity, inappropriate light cycles, and noxious aerosols, are all possible potentiating factors. Primary dermatologic disease as well as metabolic disease and parasitism may be causative. The reader is referred to the appropriate chapters in this and other references for more information.

The observation that "the best kept parrots often develop feather-destructive behavior" is applicable, and frustrated owners find comfort in this adage. With all their food, attention and security needs met, some parrots will redirect their energies. Normal preening then becomes prolonged and exaggerated and may lead to feather mutilation. Psychotropic medications seldom are a complete answer but may be used as an aid during environmental and behavioral modification.

Additionally, owners often unconsciously reward parrots for feather destruction. Psittacines may recognize the potential for feather picking or destruction to obtain internal stimulation or external reinforcement. The first step in behavioral modification is to ignore this behavior.⁴¹

The Geriatric Parrot

Despite the USA having imported hundreds of thousands of parrots in the 1970s and 1980s, there is little information to be found on geriatric parrots. Additionally, the physical and emotional health of these older import parrots may not equate to that of captive-bred psittacines that will be reaching geriatric status in the coming decades.

A study of the large macaws at Parrot Jungle (Miami, FL) found their "functional breeding life-span" to be about 30 years, and their survival life-span was about 45 years. Physical signs in older macaws included increased scaliness of feet, thickening of the skin of the feet, thinning of the facial skin, appearance of warts, cataracts and other ocular color changes. It was noted the yellow iris thinned so the dark retina could show through, producing a dark ring within the iris. Macaws over the age of 35 showed postural changes due to arthritis and degenerative neurological disease. Causes of death in these older birds included tumors, renal failure and other degenerative diseases. ¹⁶

Fig 3.3.9 | Cataract in an older yellow-naped Amazon. Cataracts may cause behavioral changes related to decreased vision.

Gradual development of cataracts allows compensation by the bird as long as its environment remains static. Sudden onset of cataracts may cause behavioral abnormalities that mimic aggression, lethargy, or even seizures (Fig 3.3.9). Thousands of imported parrots that should be growing old in captivity have died of malnutrition and husbandry related disease. Documentation of the physical and behavioral changes of our current psittacine pets as they age will improve our understanding of their medical and emotional needs. Hopefully, we will have an increasing captive geriatric parrot population from which to learn.

Conclusion

Psittacine birds have been sharing the human habitat for hundreds of years. However, these are still not domestic creatures. It will take additional research and application of existing knowledge to integrate parrots into the human environment. A growing number of owners, particularly of cockatoos, are "donating" these parrots to shelters and rescue organizations due to excessive screaming, plucking or biting behavior.³³ Other birds are condemned to life in a cage due to the owner's fear or inability to handle them. Early education of owners may prevent incompatible behaviors that lead to abandonment or neglect.

Nutritional Considerations

Section I: Nutrition and Dietary Supplementation

Section II: Nutritional Disorders

Nutritional Considerations Section I

Nutrition and Dietary Supplementation

DEBRA McDONALD, PhD, BSc (HONS I)

Selection or formulation of appropriate diets for companion and aviary birds is based on wild feeding ecology, digestive anatomy and physiology, and nutritional requirements of related species. Research indicates that requirements of some key nutrients for psittacines vary from those of poultry. Apart from vitamin E, there is no evidence to suggest that vitamin and trace mineral requirements for psittacines are greater than those recommended for poultry.54 While there are substantial differences between production species and companion bird species, dietary requirements of poultry remain the standard for estimating the needs of companion birds. Individual nutrient classes will be discussed with particular focus on recent research into the nutritional requirements of companion birds. See Nutritional Disorders, Section II of this chapter for aspects of malnutrition and nutritional diseases commonly diagnosed in companion birds.

Water

Calculated water intake of adult Australian parrots does not correlate with observed water intake (Table 4.1.1).³⁷ Desert-adapted birds require less water intake than tropical birds. Changes in diet or environmental temperatures can alter water intake.

Table 4.1.1 | Water Intake Per Day of Various Birds

Species	Body Weight (g)	Calculated Water Intake (ml)	Actual Water Intake (ml)
Budgerigar ⁸⁶	30-35	0.7-0.8	4
Canary ⁸⁵	18-24	0.4-0.6	4
Lovebird86	55	1.3	10
Cockatiel86	100	2.4	13.6
Cockatoo86	300-900	7-22	15
Amazon/Grey86	350-600	8-14	17-35

WATER REQUIREMENTS OF PSITTACINE NEONATES

The ratio of feed to water to maximize survivability in the growing chick is dependent on age; insufficient water within the first few days after hatch leads to high mortality, and insufficient solids result in slow growth rates.³¹ Studies of cockatiels indicate changes in the proportions of solids to water from 7:93 for the first 4 days after hatch, increasing to 30:70 thereafter.⁶⁵

NUTRITIONAL SUPPLEMENTATION OF DRINKING WATER

Supplementation of vitamins and minerals via the drinking water is not recommended. Water intake can vary inter- and intraspecifically and is influenced by environmental temperatures and diet. The high redox potentials of minerals, such as zinc, iron and copper, can destroy vitamins, and some vitamins are light-sensitive. It is impossible to standardize intake of vitamins via drinking water. Vitamin A and D toxicoses have been reported in macaws and conures being supplemented with liquid vitamins. To Environmental Pohydration may result if the additives decrease water intake due to unpleasant taste or unfamiliar coloration.

Energy

When calculating energetic requirements of birds, the following equations are used:

Passerine BMR kcal/day = 114.8 x kg $^{0.726}$ kJ/day = 480 x kg $^{0.73}$

Non-passerine BMR $kcal/day = 73.5 \times kg^{0.734}$ $kJ/day = kg^{0.73}$

Basal metabolic rate (BMR) is calculated from energy expended when a bird is sleeping. Perching can increase energy expenditure in budgies 2-fold; preening, eating and shuffling locomotion cause 2.3-fold increase and flight increases as much as 11 to 20 times over BMR. ¹⁰ Energy requirements of free-living birds are greater than those of their captive counterparts due to the increased energy required for thermoregulation, food procurement and territorial defense. However, the daily needs for amino acids, minerals and vitamins are relatively constant regardless of energy expenditure.

Climate can influence BMR. Psittacines from temperate climates have BMRs approximately 20% higher than those of tropical species, with seasonal changes in thermoregulation varying from 3.07 times BMR in winter (5.9° C) to only 2.77 times BMR in summer (20.7° C).¹⁰

ENERGY REQUIREMENTS

Daily consumption of calories must exceed daily energy expenditure for a sustained period in order for overweight or obese body conditions to develop. A diet for weight loss should be replete in all nutrients so that protein, essential fatty acids, vitamins and minerals are present in amounts sufficient to support normal physiological processes and to retain lean body tissue. Reducing fat content of the diet too quickly or too far has led to obsessive eating behaviors in obese double yellowheaded Amazons. Formulated calorie reduction diets generally contain lower levels of fat with simultaneous increase in indigestible fiber, air or moisture. Increased levels of dietary fiber slow gastric emptying. Insoluble fibers have a greater effect on slowing gastrointestinal

tract (GIT) transit time than soluble fibers. Fiber also increases excretion of bile acids and fat.

ENERGETIC COSTS OF MOLT

Feather replacement requires energy and specific nutrients, as well as metabolic and physiological adaptations.²⁴ Energy costs of the molt include the caloric content of the new feathers and feather sheath, the energy required in their synthesis, and the energy required to produce and maintain feather pulps. Approximately 3 to 10% of total body mass (20 to 30% total lean body mass) of passerines is replaced during a complete molt.²⁴ Daily energy expenditure of passerines undergoing a rapid complete molt can increase from 3% (early and late in the molt) to 20% (at peak molt),⁵² with BMR doubling in some passerines at peak molt.³⁴ Increases in energy expenditure due to rapid molt can be partly offset by reductions in other activities such as locomotion or singing.^{28,34}

Feathers grow throughout the day and night at similar rates, ⁵⁰ but the feather material deposited at night when most birds are fasting is of a slightly different quality. Feather synthesis at night requires complex and costly modifications to the metabolism of amino acids, compared to daytime synthesis, so the overall costs of molt may be lower in areas with relatively longer day length. ⁵¹

Carbohydrates

Carbohydrates (Fig 4.1.1) are used to produce energy in the form of adenosine triphosphate (ATP) from glycolysis

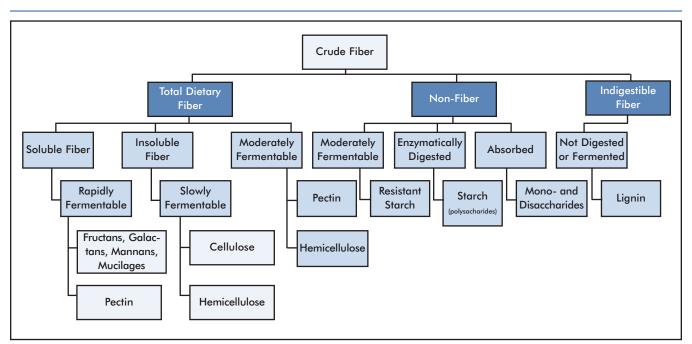

Fig 4.1.1 | Classification of carbohydrates.

and the TCA (tricarboxylic acid) cycle, and produce heat from the oxidation of glucose to CO₂ and H₂O. They are also used to produce precursors of other nutrients, synthesize glycogen or fat from glucose, decrease luminal pH through production of short-chain fatty acids, and increase the population of anaerobic flora. The antibacterial properties of short-chain fatty acids may decrease pathogenic intestinal bacteria and may be important in prevention of, and recovery from, intestinal disorders.

The central nervous system and erythrocytes require glucose for energy, in contrast to muscles that can utilize substrates such as fatty acids. In the absence of adequate dietary carbohydrates, amino acids (glucogenic amino acids via the gluconeogenic pathway) are shunted away from growth and production to be used for glucose synthesis (Table 4.1.2).

SUCRASE AND FRUIT SUGARS

Sucrose, one of the predominant disaccharides of fruit sugars (Figs 4.1.2, 4.1.3), is easily digestible. However, some insectivorous passerines, such as thrushes that feed on diets high in protein/fat and low in carbohydrate, lack the sucrase enzyme necessary for the digestion of these simple sugars. The differences in proportions of fruit mono- and disaccharides are important for species that lack the sucrase enzyme. Avoid feeding these birds fruits high in disaccharides such as mango, apricot, nectarine and peach.

POLYSACCHARIDES

While simple sugars such as the monosaccharides and disaccharides are readily absorbed, the α -bonds of starches require further digestion. Heat from extrusion processes gelatinizes the starch molecule, increasing its digestibility. The ß-bonds of some of the complex carbohydrates, such as those comprising the fibrous fraction of foods, require microbial degradation that may not be sufficient in psittacines and passerines. Cellulose is composed of ß-bonds and is generally unavailable as a source of energy, while hemicellulose consists of varying proportions of α - and β -bonds, depending on the source. Hemicellulose is therefore partially digestible without microbial breakdown, but its close association with the polyphenolic lignin often makes it indigestible. The carbohydrate content of psyllium fiber consists predominantly of hemicelluloses, so is partially digestible.

Fermentation of Polysaccharides

Postgastric microbial fermentation of polysaccharides occurs in nectarivorous, frugivorous and florivorous species. The process of enzymatic digestion taking place prior to fermentation benefits species that feed on easily digested foods such as nectar and fruit, as fermentation of nutrient-rich foods is not energetically efficient. In contrast, pregastric fermentation occurs in the hoatzin, which feeds on mature leaves, stems and branches.18 Such bulk foods are generally incompatible with flight.

Chitin

Chitin is a naturally occurring polysaccharide similar in structure to cellulose with an additional amino group. It is the principal polysaccharide of cell walls of fungi and

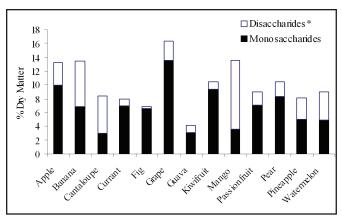

Fig 4.1.2 | Sugar content of fruits commonly fed to birds. *Require sucrase for digestion

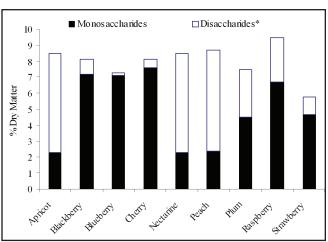

Fig 4.1.3 | Sugar content of stone fruits and berries. *Require sucrase for digestion

Table 4.1.3 | Chitin Content of Various Invertebrates and Fungi

Food Item	Chitin Content	
Fungi	5-20%	
Worms	20-38%	
Squid	3-20%	
Scorpion	30%	
Spider	38%	
Cockroach	35%	
Crab	70%	

the primary constituent of the exoskeletons of crustaceans and invertebrates (Table 4.1.3). The digestion of chitin is considered low, but it still presents a useful energy source for some species. While chitinase activity has been identified in starlings, raptors and a variety of seabirds, it is low in chickens and absent in African grey parrots and pigeons. Measurements of crude protein may overestimate protein availability for birds that lack chitinase enzymes.

Protein

Proteins are composed of the nitrogen-containing molecules, amino acids. They can be manufactured from dietary precursors (non-essential) or are required as dietary constituents (essential). Amino acids that are deemed to be essential for birds include arginine, isoleucine, leucine, lysine, methionine, phenylalanine, valine, tryptophan and threonine. In addition, glycine is known to be essential for budgerigars (*Melopsittacus undulatus*),⁷⁹ and histidine and proline are essential for chickens. It is presumed that the digestion of proteins by psittacines reflects that of poultry. Lorikeets digest only 13.3% of complete protein (egg white). ¹⁶ Digestion of proteins is more efficient in nestlings than in adult birds.

MEASUREMENT OF PROTEIN CONTENT OF FOODS

Protein values of food (crude protein) are measured using the Kjeldahl technique with the assumption that all nitrogen in the food sample is present as protein and that all proteins contain 16% nitrogen. Crude protein is calculated as follows:

$$CP (\%) = g N/kg \times 6.25$$

While this value is commonly used for converting nitrogen values to protein, it is not applicable to all foods, especially some seeds.

DIETARY REQUIREMENTS FOR PROTEIN AND AMINO ACIDS

The dietary requirement for protein varies with age and

physiological state, being highest in hatchlings and females laying large clutches, and lowest in adults at maintenance. In granivorous birds protein requirement is correlated with body size, ²⁹ with larger species such as macaws possibly requiring more protein than smaller birds. Preliminary studies with African grey parrots (*Psittacus erithacus erithacus*) indicate a protein requirement of 10 to 15% (dry matter).²⁷ Protein requirement for the adult budgerigar is 6.8% (balanced protein diet).¹⁴ Sunflower seeds, safflower seeds and peanuts are deficient in the amino acids required by poultry.⁵⁴

High fiber diets can increase fecal nitrogen content due to bacterial digestion, which can confound the results of a protein digestion study.⁶³ Nectarivorous and frugivorous species have lower obligatory protein losses. Rainbow lorikeets (*Trichoglossus haematodus*) may require as little as 2.9% protein when fed high-quality, readily digested protein.¹⁶

While high dietary protein has been implicated in renal dysfunction and gout in psittacines, studies of male cockatiels (Nymphicus hollandicus) indicate that protein levels of 20, 30 or even 70% do not result in renal insufficiency.³² However, 70% dietary protein is not recommended, as excessively high protein is strongly correlated with a significant increase in liver lesions.³² Excess protein has been associated with overgrowth of beaks and nails.35 Introduction of birds to new diets with varying levels of protein should be undertaken gradually, as sudden changes in dietary protein levels may result in nephritis and gout.32 Since birds are uricotelic, an overload of the excretory ability of the kidneys, caused by excessive intake of proteins or nucleic acids, may lead to hyperuricemia. Dehydration exacerbates this problem and may produce visceral and articular gout even without excessive dietary protein.35

PROTEIN REQUIREMENTS FOR REPRODUCTION

Protein requirements during egg production are influenced by clutch size/frequency and the protein composition of eggs. There is little taxonomic variation in amino acid composition of avian eggs.^{39,49} Protein requirements for species that lay only single eggs are similar to maintenance requirements, but that may increase if essential amino acids are lacking. Birds laying eggs require dietary amino acids for maintenance, growth of the oviduct and accretion of egg proteins, at least a week prior to the first oviposition.^{29,49} Budgerigars can maintain breeding performance on 13.2% protein. However a diet of white millet, canary seed and hulled oats (13.4% protein) containing only half the necessary lysine, methionine and cysteine is not sufficient to support reproduction.¹

PROTEIN REQUIREMENTS FOR CHICKS

Protein requirements for growth are highest at hatch and decrease over time as growth rate slows. Altricial chicks have a higher fractional growth rate and may have higher total amino acid requirements. Protein requirement for growth of cockatiels has been estimated at 20%. In addition, the protein must include 0.8 to 1.5% lysine. Many birds in the wild supplement their diets with insects, which will often provide additional protein; however, some wild birds just increase their food intake. While there is generally sufficient crude protein, lysine and arginine in commercial hand-rearing mixes for psittacines, most lack sufficient quantities of the sulphur amino acids, methionine and cysteine, which leads to stunted feather growth. So

PROTEIN REQUIREMENTS FOR FEATHERS

Feathers comprise a large percentage of total body protein (22% lovebirds; 28% budgies) with approximately 15% by mass contained in the sheath.⁵⁰ However, the amino acid composition of whole plumage differs from that of the sheath and calamus.

Dietary deficiencies in some of the sulphur amino acids cause a pronounced curvature and periodic restriction of the rachis, abnormal persistence of the basal sheath, and misshapen vanes. Feather strength is correlated with adequate dietary lysine (0.203%). Cysteine is abundant in the epidermal structure and feather barbs. While cysteine is frequently cited as a potentially limiting nutrient in the growth of plumage, cysteine reserves may be sufficient for keratin synthesis during overnight periods of fasting and short-term sulphur amino acid deficiencies. Dietary deficiencies of methionine result in dark, horizontal "stress lines" on feathers, While threefold excesses are correlated with soft, weak feathers. Tyrosine is an important factor in melanogenesis, and a deficiency in phenylalanine also impairs melanogenesis.

Production of sheaths during molt can increase protein requirements 4 to 8% per day above maintenance requirements. The additional energy required for thermoregulation may increase food intake to provide sufficient protein for feather growth without increasing the proportion of protein in the diet. A number of products on the market promoted as supplements during periods of molt are deficient in the required amino acids. The service of t

Lipids

Lipids supply energy, essential fatty acids and facilitate

the absorption of fat-soluble vitamins. In addition, they are precursors of many hormones and eicosanoids.

CLASSIFICATION OF FATS

Fats are described by the length of the carbon chain, the number of double bonds and the exact position of the double bonds. Short-chain fats contain 2 to 4 carbons, medium-chain fats 6 to 10 and long-chain fats 12 to 24 carbons. Fatty acids with 4 to 12 carbons are found in milks; those with 10 to 12 carbons are found in certain seed oils. Longer chain fatty acids are common in plants of marine origin.

ESSENTIAL FATTY ACIDS

Saturated fatty acids (SFA) are those where all carbons of the fat are satisfied with a single bond to another element. If one double bond is introduced, they are monounsaturated fatty acids (MFA). Those with two or more double bonds are polyunsaturated fatty acids (PUFA). The preferred nomenclature for fatty acids is based on the position of the double bond from the methyl end (Fig 4.1.4). For example, linoleic acid 18:2 (n-6) contains 18 carbons with two double bonds, placed six carbons from the last double bond with reference to the terminal methyl end. Higher evolved animals are unable to manufacture fatty acids of the n-3 or n-6 families and must obtain these from dietary sources. Fatty acid composition of seeds and nuts that are available for companion birds may not resemble that of wild diets (see Fig 4.1.6).

PUFA profiles are not amenable to dietary manipulation. Grains and seeds are generally rich in linoleic acid (n-6), grasses and leaves in α -linolenic acid 18:3 (n-3) and docosahexaenoic acid (n-3) (DHA). Fish and other aquatic insects are rich in 20:5 (n-3) or 22:6 (n-3).

FATTY ACIDS AND EICOSANOIDS

Certain membrane fatty acids have specific roles in the regulation of cell functions. Arachidonic acid (AA), γ -linolenic acid and eicosapentaenoic acid (EPA) act as precursors for the synthesis of eicosanoids, an important group of immunoregulatory molecules that function as local hormones and mediators of inflammation. Changes in characteristics of fatty acids available to cells modify the fatty acid composition of the membrane phospholipids of those cells and may influence inflammatory processes (Fig 4.1.5).

Cis and Trans Fatty Acids

While most natural fatty acids occur in the *cis* form (carbons on same side), processing such as extensive heat or partial hydrogenation can convert fats to the *trans* form

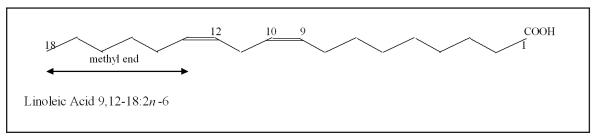

Fig 4.1.4 | Structure of n-6 fatty acid.

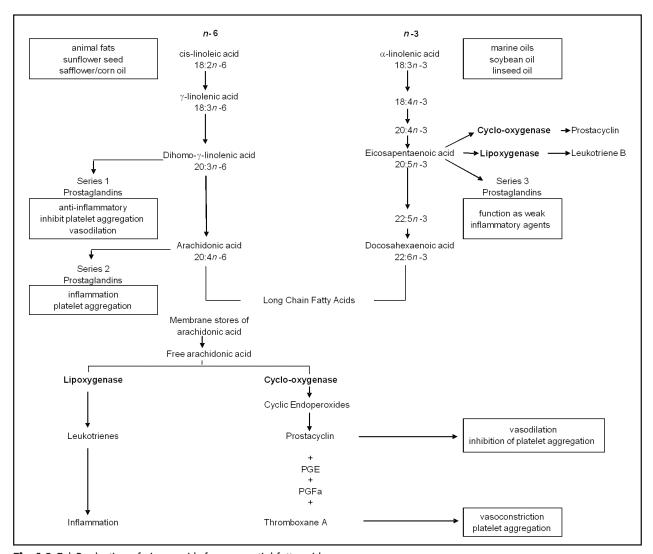

Fig 4.1.5 | Production of eicosanoids from essential fatty acids.

(carbons on opposite sides), which affects their biological activity. Although both *cis* and *trans* forms are metabolized for energy, *trans* isomers cannot function as essential fatty acids.

Antioxidants and Lipid Peroxidation

Insufficient antioxidants such as vitamin E in the feed also may enhance lipid peroxidation during storage.⁴⁸ Diets high in PUFA require additional antioxidant protection to prevent rancidity. There are a number of naturally occurring substances in food that have antioxidant properties including vitamins A, C, E, and yellow-col-

ored carotenoids such as ß-carotene.

Antioxidants help to counter the detrimental effects of oxygen-free radicals. Oxygen-free radicals have been implicated in the development of cancer, inflammatory conditions and heart disease. A deficiency of antioxidants may promote peroxidation of membrane phospholipids.

OBESITY

Obesity can lead to congestive heart failure or hepatic lipidosis and may predispose a bird to diabetes mellitus or exacerbate this illness. Body weight relative to a bird's

optimal weight has been used as a defining criterion for obesity because body weight is easier to measure than body fat. Body weight in excess of optimal body weight of 1 to 9% is acceptable, 10 to 19% is considered overweight and greater than 20% is defined as obese.

DEPOSITION OF FATS IN EGG YOLK

The yolks of precocial and altricial birds vary in lipid composition (Table 4.1.4). However, determination of specific fatty acid dietary requirements has been undertaken only on granivorus species. In contrast to fatty acid profiles of commercial grains, fatty acid composition of wild seeds on which the orange-bellied parrot (*Neophema chrysogaster*) feeds is characterized by a distinct lack of *n*-6 fatty acids (Table 4.1.5).⁴⁴

BRAIN LIPIDS

There is a surge of brain growth in the second half of the embryonic/early neonatal stage, with specific uptake of docosahexaenoic acid (DHA) by embryonic brain tissue. The selective depletion of yolk phospholipid DHA results in a range of cognitive, behavioral and visual impairments. The high proportions of amino acids in brain tissues imply a requirement for adequate levels of both n-3 and n-6 fatty acids in yolk lipids. While the avian embryo may be able to synthesize DHA from α -linolenic acid, this ability may be species-specific. Yolk lipids of the domestic chicken maintained on formulated

diets are almost devoid of α -linolenic acid, while those of the goose, pheasant and ostrich on similar diets have high levels of this fatty acid, providing sufficient precursors for conversion to DHA.

SPERMATOZOA LIPIDS

The high PUFA content of avian semen predisposes them to lipid peroxidation. Susceptibility is increased in membranes high in DHA, which is present in duck spermatozoa and can be exacerbated by low vitamin E. However, similarities in lipid peroxidation of chicken and ducks suggest the presence of high levels of antioxidant enzymes. Age-related decreases in sperm output are reduced with supplementation of 200 mg/kg vitamin E. Supplementation with longer chain essential fatty acids is also beneficial.

Vitamins and Supplementation Requirement

WATER-SOLUBLE VITAMINS

Water-soluble vitamins include the B complex and vitamin C. As dietary requirements for B vitamins have not been evaluated for companion birds, further discussion will be confined to disease entities that specifically impli-

cate imbalances in the B vitamins (see Section II Nutritional Disorders).

Vitamin C

Vitamin C (ascorbic acid) is involved in the syntheses of collagen, carnitine and catecholamine; in tyrosine, histamine, steroid, fatty acid and drug metabolism; and in the prevention of peroxidation. Birds under stress, including the stresses associated with high temperatures, growth and reproduction may have increased requirements for vitamin C.

Sources of Vitamin C

Most birds synthesize vitamin C in the kidney, liver or both. Evolutionarily, enzymatic activity occurs in the kidneys of birds in older orders and becomes localized in the liver of more advanced Passeriformes. Some passerines such as the vented bulbul (*Pycnotus* sp.) are unable to synthesize vitamin C. Vitamin C is concentrated in fresh fruits, green leafy vegetables and animal organs, with only small amounts in skeletal muscle.

Vitamin C Deficiency

Reproduction and growth increase the demand for collagen. Supplementation of 100-200 mg/kg vitamin C improves growth, egg production and eggshell strength of young chicks and hens exposed to high environmental temperatures. Dietary requirements also may vary with age, as willow ptarmigan (*Lagopus lagopus*) adults are able to synthesize sufficient vitamin C, whereas chicks require supplementation with 750 mg/kg. Berries that form part of the diet of the willow ptarmigan during the breeding season can contain up to 5000 mg/kg vitamin C.²¹

Vitamin C is susceptible to destruction with handling and processing. While it is stable when exposed to boiling water for short periods, a greater proportion is destroyed when heated at low temperatures for long periods. Any form of processing that ruptures tissue (such as freezing and thawing) exposes vitamin C to air losses due to oxidation, but vitamin C is generally stable during normal pelleting processes.

Vitamin C Toxicity

Metabolites of L-ascorbic acid such as oxalic acid can bind calcium. Excesses of vitamin C also can bind copper, resulting in growth deficiencies and increases in the incidence of aortic rupture and decreases in elastin content of the aorta if diets are also deficient in copper. It is important to minimize dietary vitamin C content for species that are susceptible to iron storage disease, as vitamin C improves the absorption of iron by facilitating the reduction of the ferric form to the more absorbable ferrous state.

FAT-SOLUBLE VITAMINS

It is important to maintain an appropriate balance with the fat-soluble vitamins as they all compete for sites of uptake. Dietary excess of one vitamin can diminish uptake and availability of another, despite adequate dietary intake.

Vitamin A

Vitamin A is involved in vision, reproduction, immunity, membrane integrity, growth, embryogenesis and the maintenance of epithelial cells. Vitamin A is of animal origin and does not occur in plant tissues. Some carotenoids can be converted to vitamin A in the intestinal wall via a specific enzyme.

Forms of Vitamin A

The most active form (retinol) is susceptible to moisture, heat and light. The retinal aldehydes are incorporated in rhodopsin and influence dim light vision. Retinoic acid supports growth and tissue differentiation but not vision. Although retinoic acid appears to play a role in testosterone synthesis, it does not support the production of sperm.

Dietary Requirement

Vitamin A requirements vary among production species (Table 4.1.6). Dietary requirements of cockatiels (*Nymphicus hollandicus*) at maintenance are 2000-4,000 IU/kg. ³⁰ Levels below 10,000 IU/kg do not significantly influence plasma levels in cockatiels. ³⁰ Dietary deficiencies of vitamin A may not impact immunocompetence for up to eighteen months in birds previously maintained on sufficient dietary Vitamin A. Dietary vitamin A can be adequately provided from 2.4 mg/kg ß-carotene in cockatiels. Recessive white canaries (*Serinus canaria*) are unable to convert ß-carotene to vitamin A and require three times as much vitamin A as colored canaries. ⁸⁸

Sources of Vitamin A

The vitamin A content of animals varies. Vitamin A levels in invertebrates are extremely low (Table 4.1.7).⁴ Fish store large amounts of vitamin A in the liver and fatty tissue. Supplementation with cod liver oil is not recommended. Seeds and nuts are generally low in carotenoids (Table 4.1.8), while some fruits can provide large quantities (Table 4.1.9).

The vitamin A content of many formulated products, most parrot foods and nectar-replacement products (Fig 4.1.7, Table 4.1.10) exceed dietary recommendations for poultry⁵⁴ and cockatiels.³⁰ While the vitamin A content of some products is higher than data reported by manufacturers, poor packaging may result in breakdown of the vitamin.⁴¹

The equivalencies are as follows:

0.6 μg β-carotene is equivalent to 1 IU provitamin A 1 RE = 1 μ g retinol = 6 μ g \(\text{\$G\$-carotene or } 12 \(\mu \text{\$g\$ of} \)

other provitamin A carotenoids

1 RE = 3.33 IU retinol = 1.818 IU vit. A palmitate = 10 IU ß-carotene

Data that is reported as $\mu g/dl$ retinol can be converted to SI units (µmol/L) as follows:

$$\mu g/dl \times 0.0349 = \mu mol/L$$

Approximately 10% of the more than 500 carotenoids have provitamin A activity.

Measuring Vitamin A

Approximately 90% of total-body vitamin A is contained in the liver. 46 Storage levels of 2-5 IU vitamin A/g liver are deemed to be adequate.46 Plasma retinol does not change dramatically with marginal vitamin A status, and reduced levels are generally not detected until animals reach a severe deficiency. It is not adequate to evaluate vitamin A status from blood samples. Liver biopsies are recommended.

Interpreting Laboratory Data

Units are reported in international units (IU) for vitamin A or retinol equivalents (RE) for provitamin A.

Signs of Vitamin A Deficiency

Clinical signs of vitamin A deficiency often resemble those of toxicity, and distinguishing between the two requires careful evaluation of dietary intake and other influencing factors. While turkey chicks exhibit signs of deficiency after only five weeks², cockatiels can be maintained on a diet devoid of vitamin A for up to two years before demonstrating clinical signs.³⁰ Signs of vitamin A deficiency can generally be classified into five categories:

Vision

Retinol is utilized as the prosthetic group in iodopsin (cones). Vitamin A deficiency results in a loss of opsin, the protein that converts vitamin A to rhodopsin, from the outer segments of the rods, leading to their eventual degeneration. Even in the late stages of vitamin A deficiency, it is possible to regenerate rods, but cones eventually disintegrate and result in blindness. Vitamin A deficiency also results in decreased secretions of tear glands.⁴⁰

Bone

A deficiency results in reduced activity of osteoclasts, leading to excessive deposition of periosteal bone by the unchecked function of osteoblasts.

Maintenance of Epithelial Tissue

Dietary deficiencies of vitamin A can alter the permeability of lipoprotein membranes of cells and intracellular particles. Low levels of liver vitamin A are correlated with symptoms of focal metaplasia of the excretory duct as well as the glandular epithelium of salivary glands. Loss of membrane integrity also interferes with water retention, and renal uric acid deposits can result. Coccidiosis can lead to the destruction of vitamin A in the gut and injure microvilli of the intestinal wall, decreasing the absorption of vitamin A.⁶⁹ Vitamin A deficiency in chicks is characterized by poor feathering on the head, neck and breast regions, as well as facial dermatitis.

Reproduction

Defects in reproduction, including increased time between clutches, reduced hatchability, increased embryonic mortality, decreased survival time of progeny, decreased testes size, failure of spermatogenesis and a decline in sexual activity in males, are correlated with deficiencies of vitamin A. These may be associated with failure to maintain healthy epithelium.¹⁷

Immune Function

Both deficiency and excess of dietary vitamin A suppress immune function. Vitamin A deficiency in chicks leads to a rapid loss of lymphocytes. Diarrhea, pneumonia and blunted immune response are characteristic of vitamin A deficiency in cockatiels.³³ Deficiencies lead to phagocytic activity in macrophages and neutrophils, and impair intestinal IgA response.³³

Vitamin A Toxicity

In the wild, noncarnivorous birds are rarely exposed to dietary excess of vitamin A. These birds probably depend on the conversion of carotenoids to biologically active vitamin A. Toxicities are avoided because the efficiency of conversion of vitamin A from ß-carotene decreases with higher levels of intake. Conversion efficiency in the chicken drops from a ratio of 2:1 to 5:1.46 Studies of Japanese quail also indicate a saturation of the retinol-transporting system, as birds supplemented with ß-carotene do not develop increased levels of retinyl palmitate.60 Cockatiels at maintenance are more susceptible to vitamin A toxicity than deficiency.30 Perhaps ß-carotene would be a superior source of vitamin A in some psittacine diets; however, ß-carotene may not be appropriate for hand-rearing mixes because chicks may not efficiently convert ß-carotene to vitamin A. Toxicities have been reported in cockatiels maintained at 10,000 IU/kg of vitamin A. Many commercial diets exceed this level. 30 Some hand-rearing diets have levels in excess of 47,000 IU/kg.85 In lorikeets, commercial diets high in vitamin A and deficient in vitamin E are correlated with high rates of infertility, decreased hatching and survivability of chicks. 42 The author hypothesizes similar levels may contribute to the increased incidence of iron storage disease in these birds. Vitamin A toxicity causes epithelial damage and keratinization of squamous cells.33 Epithelial damage results from penetration of retinol into the lipid portion of the membrane, causing it to expand. Weakening of the membrane results from the inelastic protein portion of the membrane resisting expansion and increases access to pathogens and infection. Clinical signs of Vitamin A toxicity include:

Vocalization Patterns

Cockatiels maintained on excess dietary vitamin A exhibit frequent stress calls of greater intensity and duration.³⁰ Vitamin A toxicities may contribute to behavioral problems in companion birds. Vocalization changes were observed in psittacines maintained on diets that contained recommended levels of vitamin A.^{47,75}

Iron Storage Disease

See Section II Nutritional Disorders for the potential contribution of excess vitamin A to iron storage disease. Splenic hemosiderosis has been correlated with excess vitamin A in cockatiels.³⁰

Pancreatitis

Pancreatitis was diagnosed in cockatiels fed excessively high levels of vitamin A.³³ Hypervitaminosis A increases the activity of sucrase and eliminates the duodenum's ability to regulate this enzyme in the small intestine⁷¹ which may lead to diabetes and digestive difficulties.

*UVB is the biologically active ultraviolet light

Reproduction

Excesses of vitamin A may interfere with uptake of vitamin E, compromising fertility, hatchability and survivability of chicks.

Antioxidant Status

Vitamin A supplementation of laying hens increases liver, egg yolk and embryonic liver concentrations at the expense of vitamin E, compromising the antioxidant status of progeny. High levels of vitamin A reduce uptake of astaxanthin, a powerful carotenoid antioxidant that protects mitochondria from damage by Fe⁺² catalysed lipid peroxidation.

Vitamin D

Vitamin D is a group of closely related compounds that possess antirachitic activity. They are obtained directly from the diet or from irradiation of the body. The two major natural sources (provitamins) are cholecalciferol (D_3 in animals) and ergocalciferol (D_2 , predominantly in plants). Both D_2 and D_3 forms also can be ingested and further metabolized to 25-hydroxyvitamin D_3 through hydroxylation first by the liver, and then again to 1,25-

dihydroxyvitamin D₃ in the kidneys. Cholecalciferol can be produced in the skin of most mammals from provitamin 7-dehydrocholesterol via activation with ultraviolet light in as little as 11-15 minutes daily. Vitamin D enhances intestinal absorption and mobilization of calcium and phosphorus through the hormone 1,25-dihydroxyvitamin D₃. Circulating levels of 25-hydroxyvitamin D₃ are indicative of vitamin D status. One IU of vitamin D activity is equivalent to the activity of $0.025 \mu g$ vitamin D_3 . As vitamin D_2 has only 1/10 the activity of vitamin D_3 in chicks the International Chick Unit (ICU) is used with reference to vitamin D₃ in poultry. Plasma half-lives vary with the form of the vitamin ranging from 5 to 7 days (vitamin D) to 20 to 30 days (25-(OH)D₃) (see Chapter 5, Calcium Metabolism). In mammals and reptiles, activation depends on UVB radiation (290-320 nm) (Table 4.1.11).

Dietary Requirement

The dietary requirement for vitamin D in poultry is 200 IU/kg. While higher dietary requirements are evident for the turkey (900 IU/kg) and Japanese quail (1200 IU/kg), optimum levels for companion birds have yet to be established. It has been suggested that dietary levels for poultry are adequate for breeding African grey parrots⁷⁶ (Table 4.1.12), but many formulated foods exceed these levels.

Vitamin D Deficiency

Vitamin D synthesis can be affected by liver malfunction; intestinal disorders can reduce absorption of the vitamin and kidney failure can prevent synthesis of 1,25-(OH)₂D₃. Inadequate exposure to UVB radiation prevents production of vitamin D in the skin. Glass windows block the penetration of UVB rays. The first signs of vitamin D deficiency include decreased egg production, thinning or

absence of eggshells, and an increased incidence of embryonic death. Inadequate maternal transfer of vitamin D_3 and 25-(OH) D_3 results in the failure of development of the upper mandible and failure to pip.

Vitamin D Toxicity

Vitamin D toxicity may arise from an excess of dietary vitamin D or a deficiency in the other fat-soluble vitamins. Toxicity leads to widespread calcification of soft tissue. Toxic levels can be transferred maternally to the embryo, leading to abnormalities in chick development. Safe upper limits in chicks less than 60 days old are 40,000 IU/kg and 2800 IU/kg in birds older than 60 days.

Vitamin E

Vitamin E consists of tocopherols and tocotrienols in four isomeric forms, α , β , δ , and γ . α -tocopherol has the highest vitamin E activity followed by β , δ and γ , respectively. Dietary requirements of vitamin E are dynamic, with increased requirements with diets high in PUFA, oxidizing agents, vitamin A, carotenoids, trace minerals and decreased requirements in diets high in other fat-soluble antioxidants, sulphur-containing amino acids and selenium. Vitamin E is one of the least toxic vitamins, however, high doses decrease absorption of vitamins A, D and K, resulting in reduced hepatic and egg yolk storage of vitamin A,77 impaired bone mineralization20 and coagulopathies.53 Studies of pelicans indicate that 500-10,500 IU vitamin E/kg result in decreased growth and coagulopathy.⁵³ Japanese quail under heat stress (34° C) require 250 mg/kg vitamin E and 0.2 mg/kg Se.66 Various researchers have recommended up to 60 mg α -tocopherol per gram of PUFA. Many formulated foods have less than 200 mg/kg of vitamin E. Vitamin E status can be evaluated from single blood samples, but the magnitude of body stores may not be reflected in α -tocopherol concentrations. 45,81 High dietary concentrations of vitamin E elevate vitamin E levels in the blood. Deficiencies affect the neuromuscular, vascular and reproductive systems.

Vitamin K

Vitamin K plays a major role in blood clotting factors and is involved in the synthesis of osteocalcin, with deficiencies resulting in increased bleeding times and toxicities resulting in kidney tubule degeneration. Vitamin K is available as phylloquinone (K_1) from plants, menaquinone (K_2) from bacteria and menadione (K_3) which is synthetic. Vitamin K_1 is present as the fat-soluble portion of plant chlorophyll (Table 4.1.13). An energy-dependent process absorbs vitamin K_1 from the intestine, whereas vitamins K_2 and K_3 are passively absorbed. Estrogens stimulate the absorption of vitamin K_1 . Vitamin K_3 has twice the potency of natural vitamin K_1 on a weight-to-weight basis. Vitamin K_3 is the most common form in commercial

bird foods. Choline can impact the activity of water-soluble K_3 , destroying up to 80% within 3 months. γ -irradiation of foods to increase storage life also inactivates vitamin K, while heat treatment can increase its bioavailability (Table 4.1.14).

It has been suggested that mortality from cerebral hemorrhage in some species of fig parrots (*Opopsitta* spp.) is the result of dietary deficiency of vitamin K. ¹¹ If fig parrots have developed a dependency on vitamin K_2 produced by the gut microbes of termites, they may be unable to process sufficient vitamin K_1 from plant sources. Daily supplementation of 300 μ g vitamin K_1 per fig parrot appears to alleviate clinical signs. ¹¹

Nutritional Influence on Feather Pigmentation

The dietary pigments utilized by passerines for their coloration are referred to as carotenoids. Psittacines do not use carotenoids for feather pigmentation. Each carotenoid produces a specific color. Carotenoids are subdivided into carotenes and xanthophylls (Table 4.1.15). Carotenoids may be used directly in the plumage or modified to other forms prior to incorporation into the feathers or skin (Fig 4.1.8, Tables 4.1.16-4.1.18). Each carotenoid appears to have its own individual pattern of absorption, plasma transport and metabolism. There are considerable species differences in the types of carotenoids that are preferentially absorbed and metabolized. Many carotenoids act as potent antioxidants and stimulate the immune system.

The yellow pigmentation of the helmeted honeyeater

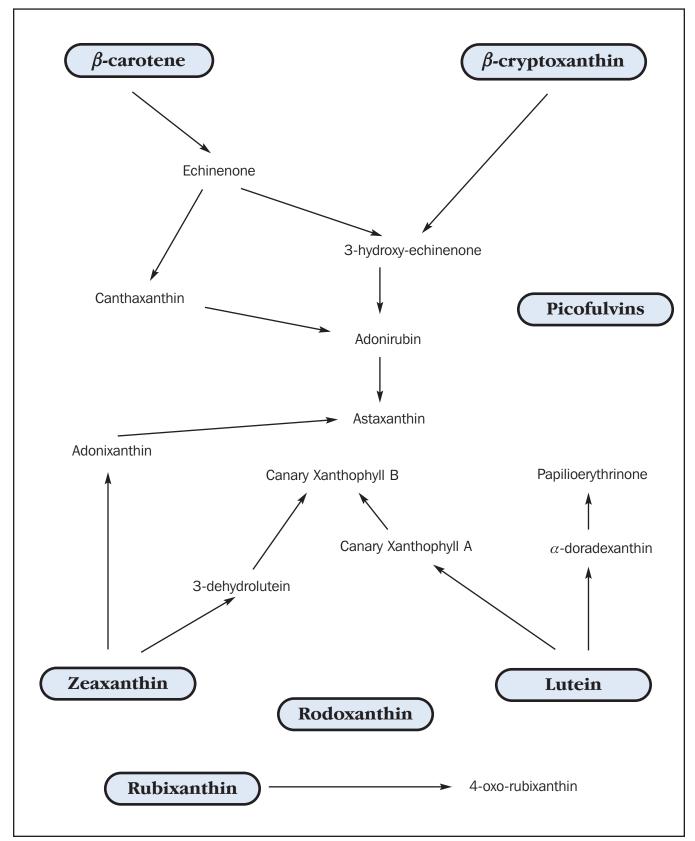

Fig 4.1.8 | Metabolic pathways for various dietary carotenoids. Rodoxanthin and picofulvins are deposited directly from the food into the feathers and are not metabolically transformed.

(Lichenostomus melanops cassidix) (Fig 4.1.9) is replaced with near white pigmentation (Fig 4.1.10) when maintained on commercial nectar mixes high in vitamin A. Feather structure and light refraction can influence feather color. Carotenoids also can act synergistically with melanin pigments. Dark colors (black, brown, gray and related tints) produced by melanin and porphyrin pigments complexed with trace minerals are influenced by amino acid nutrition. Stress can influence feather quality and color.

Minerals

CALCIUM AND PHOSPHORUS

Adequate dietary calcium can be negated by high phosphorus content. The dietary ratio of Ca:P should range

from 1:1 to 2:1.61 Calcium availability can be influenced by solubility and particle size. Foods high in oxalic acid form insoluble calcium oxalates, while phytates bind phosphorus and decrease its availability. Additional oxalic acid can be produced from excesses of vitamin C. Fats can form insoluble calcium soaps.

The calcium content of nuts and seeds is variable (Fig 4.1.11). Some green leafy vegetables and tubers that are high in calcium also are high in oxalic acid (Figs 4.1.12, 4.1.13), which decreases the calcium availability.

Invertebrates generally have poor Ca:P ratios (Toble 4.1.19). Crickets should be maintained on 80% poultry mash and 20% calcium carbonate. Water should be provided *ad lib* from produce (such as a slice of apple) or free water. If die-off of crickets occurs from constipation, restrict gut loading to 48 hours prior to feeding. When

feeding whole vertebrate prey, it is not necessary to supplement with calcium (Fig 4.1.14).

It has been suggested that optimum levels of calcium in feed are between 0.3 to 0.7%. Many wild seeds provide 0.1 to 0.3% calcium (Table 4.1.20). Companies continue to provide formulated feeds in excess of 0.7%. It is possible that the high calcium content of formulated foods contributes to the development of renal disease that is observed in color mutation cockatiels.

IRON

Body iron is either hemal or non-hemal (Table 4.1.21). Hemal iron forms part of the porphyrin group and comprises 70 to 75% of total iron. Iron from animal sources is generally more available than that from plant sources. Iron in soy isolates may be unavailable. Pectin, vitamins A and C, and amino acids such as cysteine, histidine and lysine enhance iron uptake. High levels of calcium and/or phosphate decrease iron absorption in chicks. Cellulose and oxalate, as well as the heat and pressure of food processing, increase the bioavailability of iron. (Tables 4.1.22-4.1.25).

SELENIUM

Selenium (Se) and vitamin E function synergistically as

Table 4.1.20 | Calcium Content of Wild Food Resources of the Orange-bellied Parrot⁴⁴

Species	Common Name	Calcium (%)	Seed Weight (mg)
Mainland Indigenous			-
Halosarcia pergranulata	Black-seed glasswort	0.1	0.3
Samolus repens	Creeping brookweed	0.68	0.017
Sarcocornia quinqueflora	Beaded glasswort	0.28	0.3

Gahnia grandis	Brickmaker's sedge	0.3	7.7
Restio complanatus	Flat cord rush	0.2	0.5

antioxidants; the actions of vitamin E cannot be replaced with selenium. Selenium toxicity decreases hatchability, growth and reproductive success and results in deformed embryos, diminished immune function, abnormal feather loss, emaciation and liver lesions. 23,74 Dietary selenium affects whole blood levels.56 Mallards fed more than 10 mg/kg Se developed bilaterally symmetrical alopecia of the scalp and dorsal cervical midline, broken nails and necrosis of the tip of the beak.⁵⁶ Chicks raised on diets depleted of both vitamin E and Se show signs of exudative diathesis on the superficial pectoral muscles. Deficiencies of selenium are characterized by increases in heterophils and decreases in lymphocytes, basophils and hemoglobin. Selenium deficiency depresses plasma T₃ concentrations.25 Dietary selenium up to 0.4 mg/kg appears to be adequate for large psittacines maintained on extruded diets with 200 mg/kg vitamin E.43

ZINC

Zinc is involved in cell replication and in the development of cartilage and bone. Normal serum zinc concentrations reported for parrots range between 0.5 and 5.8 ppm (7.65-84 µmol/L). 82,45 However, plasma and serum concentrations above 2 ppm (30 µmol/L) have been considered diagnostic for zinc toxicity in most species. 5.15.55.59,72,82 A lack of correlation between hepatic zinc levels and clinical diagnosis of zinc toxicity also has been reported. 12

Zinc toxicosis usually arises from ingestion of zinc-coated aviary wire or metallic foreign bodies. 62 Clinical signs of zinc intoxication include anorexia, acute gastroenteritis, ataxia, lethargy, yellow-colored feces, vomiting, extreme loss of plumage and hepatomegaly. 72,85 It can cause pancreatic cell necrosis. 72 Excess dietary zinc negatively impacts tissue concentrations of α -tocopherol. 36 Zinc is more toxic in iron-deficient chicks than in properly iron-supplemented birds. $^{6.55}$ Liver biopsy is

not definitive as a diagnostic tool (Table 4.1.26). Signs of zinc deficiency include reduction in immune response, alterations to cell division, early embryonic death, fetal abnormalities, weak chicks at hatching, retarded growth, alopecia, dermatitis, delayed sexual development, abnormal skeletal formation and feathering.

Specific Diets

FRUIT AND POLLEN

Nectarivorous birds feed on a variety of pollens, plants, insects and their exudates. 9.19.57.89 Pollen is high in protein

(Table 4.1.27), while its digestibility is relatively low in hummingbirds and lorikeets (4.5-6.6%).⁸ As the sugar content of fruits increases, the volumetric intake and passage rate decrease.⁸⁴ The protein content of fig species is variable (4-25%).²⁶

WHOLE PREY

Whole prey fed to birds in captivity can differ from that available in the wild (Tables 4.1.28, 4.1.29; Figs 4.1.15, 4.1.16). and may require supplementation. Feeding individual pieces of prey or eviscerated meat can contribute to nutrient imbalances. Feeding high proportions of liver can result in hypervitaminosis A. Supplement meat-based diets with CaCO₃, which has

the highest calcium content (Table 4.1.30).

INSECTS

There are limited varieties of invertebrates for captive birds, with mealworms, earthworms and crickets forming the bulk of the available diet. Hard-bodied insects that contain up to 50% of their body weight as chitin may be important sources of dietary fiber, as chitin is

chemically similar to cellulose. Chitinase activity has been identified in starlings, raptors and a variety of seabirds. Vitamin E content of many insects is adequate, but vitamin A content is relatively low or undetectable (Table 4.1.31). Insects (especially from colder climates) contain high levels of polyunsaturated fatty acids. Insects generally concentrate a number of carotenoids that may be important for pigmentation or antioxidant activity. Insects generally have poor Ca:P ratios (Table

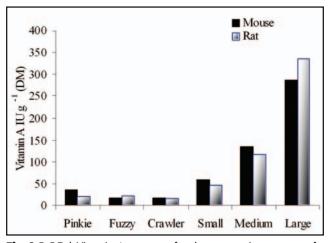

Fig 4.1.15 | Vitamin A content of rodents at various stages of development.

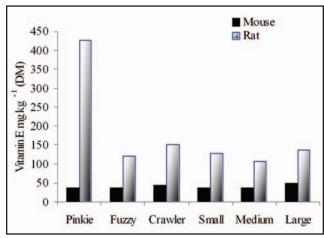

Fig 4.1.16 | Vitamin E content of rodents at various stages of development.

4.1.32). Calcium content of termites is low, but the content of their nest material (1.7%) provides a valuable source of calcium to birds, such as fig parrots, that nest in termitaria.⁷⁰

FISH

Fish must be stored below -18° C to maintain nutritive value. Fish should be dry-thawed at <4° C up to 48 hours before use, and emergency thaws should be undertaken in plastic bags under cold running water to prevent the loss of nutrients. Supplementation of piscivorous diets is required for some key nutrients, depending on the species of fish fed and the method of preparation. Feeding whole fish is imperative to maintain proper Ca:P ratio. Iodine content of marine fish is considered adequate (0.9 mg/kg), while that of freshwater fish may be as low as 0.03 mg/kg. Sodium levels of marine fish are adequate if fish are not thawed in fresh water. Heat stress may increase a bird's sodium requirement. Vitamin A content of fish commonly fed to birds is adequate (Fig 4.1.17). Supplementation may be required if eviscerated fish are fed. Vitamin E levels of frozen fish are generally inadequate (Fig 4.1.18). Thawing of fish in water will deplete water-soluble vitamins. However, there is no data to support the supplementation of fish with water-soluble vitamins other than thiamine (B₁) if they are dry-thawed. Many fish contain thiaminase; these require 25 to 30 mg of thiamine per kg of fish fed.

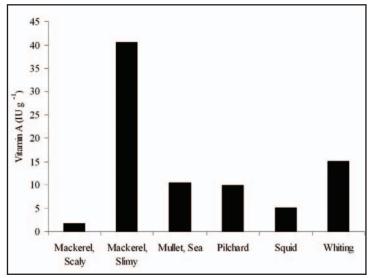

Fig 4.1.17 | Vitamin A content of fish stored in a frozen state (-10°C).

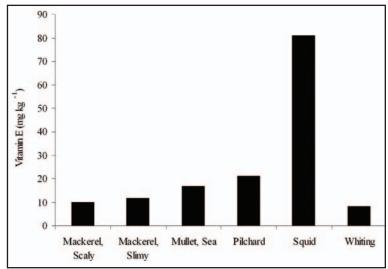

Fig 4.1.18 | Vitamin E content of fish stored in a frozen state (-10°C).

Labeling

Most products will display information regarding only a "guaranteed analysis." This provides an indication of maximum or minimum levels of crude protein, fat and fiber. However, there is no legal requirement for every batch to be chemically evaluated, rather these values often are derived from calculated values and thus may not be accurate. Furthermore, a value for "crude protein" provides no information about the digestibility of the protein or the proportions of various essential amino acids. A crude protein value for products containing invertebrates does not account for the proportion of nitrogen bound up in chitin. A crude fat content indicates neither whether the fats are saturated or unsaturated, nor the proportions of essential fatty acids. A crude fiber value does not delineate the proportion of soluble or digestible fiber, and provides no information about the lignin content.

SUMMARY

Nutrition is the single most important aspect of bird husbandry. Nutrition impacts the health, longevity, appearance and behavior of birds in captivity. The complex biochemistry and interactions between levels of nutrients coupled with the paucity of research in companion birds make choosing an appropriate diet very difficult.

Species differences between various psittacines makes dietary recommendations even more complex. Table 4.1.33 offers current estimated nutritional requirements for psittacines. A summation of critical factors in the selection of a diet should include:

- 1. Consideration of any species specific dietary requirements or sensitivities.
- 2. Avoidance of excessive amounts of nutrients, as well as assuring adequate mineral levels.
- 3. Analysis of the components and availability of the

Table 4.1.33 | Estimated Nutritional Requirements for Psittacines

[°]Calcium requirements established for budgerigars, some species may have higher requirements.

listed manufacturers, "crude" protein, fat, calcium, etc., and knowledge of what method is used to measure these levels.

- Awareness, as in human, dog and cat nutrition of the potential dangers inherent in preservatives and additives.
- Recognition of the discrepancy between wild natural food sources and substitutions made by many commercial manufacturers.

Nutritional Considerations Section II

Nutritional Disorders

GREG J. HARRISON, DVM, Dipl ABVP-Avian, Dipl ECAMS DEBRA McDONALD, PhD, BSc (HONS I)

Nutritional disorders can result from malabsorption, a deficient diet, over-supplementation and/or overeating. Deficiencies and excesses of nutrients can both be harmful to birds.

Companion birds have been maintained for decades on diets that, while nutritionally inadequate, support limited breeding in a few species. While there are numerous publications regarding nutritional requirements of agricultural species, captive passerine energetics and feeding ecology, there are few controlled scientific studies on aviary and companion birds or their wild conspecifics. Variations in lifestyle and breeding ecology result in differing nutritional requirements. Clinically, many health problems are correlated with nutritional disorders. This chapter will provide an overview of these conditions observed in companion birds, with reference to anecdotal observations in a clinical context and summaries of nutrient implications that have been predominantly studied in agricultural species. Specific studies of companion and wild birds will be discussed. Parallels may exist between the following description of the improper diet cascade and the metabolic syndrome of humans and rats.90b

The Improper Diet Cascade (IDC)

The 'improper diet cascade' (IDC) (Table 4.2.1) has been postulated by the author (GJH) from decades of clinical experience, reports from pathologists and nutritionists, as well as consultations with companies that produce commercially formulated diets. The IDC expresses itself in a highly individualistic fashion. The most common

thread is the history of a basic seed and table food diet. Generally, at presentation of a "sick" bird, the IDC patient exhibits pansystemic clinical signs that often include various behavioral problems. Typically though, the earliest clinical signs are reflected in the integument, followed closely by the digestive system. Often birds are not presented for evaluation until the reproductive or respiratory system is affected. Behavioral problems can be the proximal cause of veterinary presentation when other clinical signs have been missed or ignored.

The IDC can be initiated from a nutrient imbalanced diet as well as from influences, such as improper husbandry, diet handling and storage or over-supplementation of nutrients in formulated diets. Therefore, when evaluating nutritional disorders, consider the composition of the diet eaten, as well as the stability or availability of nutrients in that diet. Pathological influences such as parasite infestation, metal toxicoses, malabsorption syndromes, pancreatitis and gastroenteritis produce clinical signs similar to those seen in IDC, and therefore need to be ruled out (Table 4.2.2a).

The IDC is the result of improper nutrient utilization, usually from malnutrition that weakens the body immunologically and structurally. This can allow invasion of low level pathogens or commensals of viral, bacterial, or fungal origin.

Recent research by Dr. M. Beck, University of North Carolina¹⁵, showed that when the host is affected by a nutritional deficiency, the invading pathogen is affected as well. By sequencing the viral isolates recovered from selenium-deficient mice, she demonstrated mutations in the viral genome associated with increased pathogenesis of the virus affected by nutrient deficiency. Bhaskaram

Diet constituents interfere with nutrient utilization	Improper food packaging/handling or storage		Metal toxicosis

expanded this theory by showing that several micronutrients such as vitamin A, ß-carotene, folic acid, vitamin B₁₂, vitamin C, riboflavin, iron and selenium could be involved in such a scenario in humans. 17 These micronutrient-compromised viruses can lead to the emergence of new infections.¹⁷ This hypothesis was further advanced by Lavender61, who showed that, at least for RNA viruses, host nutrient deficiencies and excesses can influence the genetic make-up of the pathogen. The majority of viruses are RNA viruses.61

The importation of wild caught psittacines has traditionally involved weeks to months of stress including severe nutrient imbalance. Such birds imported into the USA in the 1970s and 1980s were a part of a pandemic of new viral diseases. Psittacine beak and feather disease, proventricular dilatation disease and papillomatosis are three that still plague us. The research community has not adequately addressed the role of malnutrition in viral pathogenesis. It is interesting to ponder this hypothesis in light of the new expressions of these same viruses occurring in the European Union countries that still import wild-caught birds.

IMPROPER DIET FORMULATION

There is a general perception that 'fresh' is best. However, presenting a bird with an array of fresh produce, seeds and nuts does not necessarily provide a nutritionally balanced diet. Commonly fed seeds are deficient in a number of nutrients (Table 4.2.2b). Much of the produce is sold in its immature state of growth, and even when mature, it does not have the equivalent nutrient profiles of wild food items. Thus such produce is unable to improve the nutrient profile of the diet.

It is imperative that bird owners be informed of the nutritional inadequacies of such diets. In the wild, psittacines usually balance their diets by feeding on a variety of seeds and other plant parts. Primary issues of concern with captive diets are vitamin levels (vitamins A, D, E, and K and the water-soluble vitamins-biotin and B₁₂) and minerals. Seeds do not contain vitamin A and are generally low in the vitamin A precursor ß-carotene. Hypovitaminosis A is particularly prevalent in birds on all-seed diets. Mineral levels of seeds can vary among plant species as well as geographically, depending on the composition of the parent soil. Calcium is deficient in most seeds and, while adequate phosphorous may appear to be present, up to 70% may exist in phytate form that is generally indigestible. Fatty acid composition will also vary among seed species and an imbalance can be an important cause of a number of health issues. Many seeds provide adequate total protein but do not contain the complete set of essential amino acids. A diet of predominantly millet seed will result in a lysine defi-

Table 4.2.2b | Nutrient Deficiencies of Seeds

The seeds most commonly fed birds, such as oats, corn, sunflower, safflower and millet, are generally missing 32 ingredients (from eight groups) needed to keep birds healthy. These include:

- Vitamins choline, niacin, pantothenic acid, riboflavin (B₂), cyanocobalamine (B₁₂), biotin (H), D₃, E, K, and folic acid (M)
- Minerals calcium, phosphorous (70% tied up as nondigestible phytates in plant products, such as grains),
- Trace minerals selenium, iron, copper, zinc, manganese, iodine, chromium, vanadium, bismuth, tin, boron
- Pigments chlorophyll, canthaxanthin
- Protein (amino acids) lysine, methionine
- Fiber (mucopolysaccharide) both soluble and insoluble
- Vitamin precursors ß-carotene, converted to vitamin A in liver
- Omega 3 Fatty Acids

ciency not seen on other seed-based diets. The composition of commercially raised seeds differs dramatically from wild seeds (see Section I of this Chapter).

Birds do not exhibit nutritional wisdom when selecting dietary ingredients; they show a preference for highenergy, lipid-rich seeds, high carbohydrate seeds and fruits. The advent of formulated foods has diminished the incidence of nutritional disorders in the author's (GJH) practice. Yet not all formulated diets are created equal (Tables 4.2.2c-e). For example, products that offer the opportunity for selecting favored food items are poorly formulated and can be just as imbalanced as a seed-based diet in the end.

The Association of Avian Veterinarians (AAV) formed a committee of nutrition experts who developed a list of recommendations to assist veterinarians and owners in feeding pet birds (Table 4.2.2f).

While some essential nutrients are higher in organically certified plant products, a diet composed solely of organic seeds will present as many nutritional problems as a diet solely composed of non-organic seeds.

There are also the issues of diminished availability of some nutrients by interference from other nutrients and potential breakdown of key nutrients.

OVER-SUPPLEMENTATION

Vitamin toxicity is an aspect of dietary management that is frequently overlooked, but can be responsible for a number of clinical signs of a disease. Many commercially formulated products contain excessive levels of the fatsoluble vitamins A and D. The addition of vitamin supplements with high concentrations of these two vitamins compounds that excess. The generally low levels of

Addition of artificial coloring/dyes long term effects unknown	Soft plastics may act as phytoestrogens	Degradation of nutrients
	be toxic or teratogenic. However, in the to maintain quality and prevent rancid	

vitamin E in both commercial diets and vitamin supplements may exacerbate toxicity. Dietary supplementation should be undertaken only if there is an extensive knowledge of the nutrient composition of both the diet and the supplement. The common clinical practice of injecting vitamins into sick birds may not be defensible, especially if the bird has been on a formulated and/or supplemented diet. See Section 1, Nutrition and Dietary Supplementation for a more in-depth discussion.

RANCIDITY

Altering tissue structure mechanically (hulling, grinding, and crushing in the case of vegetable matter or maceration in the case of animal tissue) releases lipases.

Grains damaged at harvest also allow this lipase release to occur. Similarly, micro-organisms (fungal contaminants) contain lipases that cause hydrolysis of fats.^{43b} So

quality control of source products is essential. The exposure to oxygen, moisture and heat act with the catalysts naturally present in grains (iron, copper) to accelerate the deterioration process at all stages of grain handling and product manufacturing.

These lipolytic enzymes act on lipids to release free fatty acids and triglycerides. In the presence of oxygen, heat and moisture, these fatty acids and triglycerides are auto-oxidized or acted upon by enzymes (primarily stored in the germ) called lipoxygenases. Polyunsaturated fatty acids (oleic, linoleic, and linolenic) are the most likely to be oxidized, and they are usually the most abundant fatty acids in nuts and seeds. This oxidation process produces free radicals in a dark environment. A similar but slightly different reaction occurs when exposed to light. Both reactions end with the production of lipid hydroperoxides which further break down, causing rancidity. This process is often self perpetuating, starting

Table 4.2.2f | AAV Feeding Brochure

Association of Avian Veterinarians Feeding Recommendations

FEEDING COMPANION BIRDS

Feeding of companion birds has been one of the most challenging aspects of their care, primarily because of limited nutritional research on all species. However, based on studies of poultry and other animals, generalizations can be made on adequate feeding practices for companion birds.

FORMULATED DIETS

Formulated bird food products are available from the pet food industry as a convenience to the owner and to ensure a more nutritionally balanced diet than that offered by seeds alone. The current trend is toward specific formulations addressing age, activity, therapeutic, and stress-related needs of the bird. For example, birds have special nutritional needs during molting, egg laying, or raising young. However, improving a diet in the short term in anticipation of these life stages is not effective; the feeding practices must be optimal year round.

Commercial bird food products may be purchased as pellets, nuggets, crumbles, or hand feeding premixes. Converting a seed-eating bird to a formulated diet must be done with care because new items in the cage may not be immediately recognized as food. Your veterinarian can recommend a commercial formulated bird diet and help you with the conversion process.

ALTERNATIVE HOMEMADE DIETS

Where commercial diets are not available, attempts are made to produce a homemade diet. While not ideal for pet birds, these usually offer an improvement over an exclusive seed diet. Overall, however, homemade diets are often lacking in calcium, iodine, selenium, protein, fatty acid balance, fiber, pigments, and vitamins A, B complex, E, and D, while providing an excess of carbohydrates, and phosphorus. Additionally, homemade diets with moist ingredients tend to spoil easily and lose nutrients if not stored properly or if made too far in advance of feeding. The time and effort involved in preparing foods and the difficulty in balancing the nutrients make homemade diets impractical for the pet bird owner. Owners choosing a fresh food plan tend to offer too much variety and quantity of food each day, permitting birds to pick out what they like. Birds will not choose a balanced diet if given free choice. Consult your avian veterinarian for specific recommendations on items and quantities to feed.

FRESH WATER

Fresh water must be provided at all times. Some aviculturists and companion bird owners have had success using pet water bottles for birds, thereby limiting soiling of water.

FEEDING TIPS

- Carefully monitor TOTAL food consumption during any diet change.
- Introduce small amounts of a new food at a time.
- Gradually reduce the total volume of seeds as you increase the volume of more nutritional foods.
- · Clean all food and water cups and remove old food from the cage daily.
- · Do not provide supplemental vitamins unless recommended by your avian veterinarian.

BEHAVIORAL ENRICHMENT

A consistent daily feeding program contributes to physical and mental health as much as a varied diet. The availability of natural items such as branches, empty nutshells, leather pieces and coconut shells create a stimulating environment.

GRIT

Grit is small non-dissolvable rock. The necessity of grit in the diet is debatable. Some birds, such as pigeons, fowl, canaries and finches, appear to need the availability of grit. In psittacine species, an occasional grit particle is harmless but it is not necessary for healthy maintenance of pet parrots, macaws, parakeets and similar species.

SALT

Salt licks are not necessary for birds.

DEPRAVED EATING HABITS

Birds that routinely eat inappropriate materials (eg, feces, enclosure substrate) should be examined by a veterinarian. This behavior may be associated with disease or nutritionally deficient diets and is often prevented by the feeding of a more balanced formulated food product.

SPECIAL REQUIREMENTS

Lories and lorikeets require specialized diets in captivity. These nectar diets attract insects and result in liquid and messy feces. Your avian veterinarian can recommend a diet for these species. Soft-billed birds, waterfowl, backyard poultry and gamebirds Commercial foods are available for these birds. Some toucans and mynahs may have a special dietary requirement for a low-iron formula. Consult your avian veterinarian for recommendations.

slowly and increasing rapidly as reaction chemicals become available.

Expressing the oil from seeds increases the surface area being exposed to oxygen, which can increase the possibility of rancidity occurring.

The production of lipid hydroperoxides does not appear to alter flavor. Lipid hydroperoxides deteriorate to aldehydes in the presence of oxygen. 43b These do alter flavor and finally palatability. Alcohols and hydrocarbons are also produced. These latter products have been reported to be mutagenic.16 Rancid fats can lead to selenium and vitamin E deficiencies implicated in encephalomalacia, pancreatitis, myocardial necrosis, hepatic necrosis and general myopathy. Biochemical analysis of affected birds' blood may show anemia, elevated lactate dehydrogenase (LDH), aspartate aminotransferase (AST), creatinine phosphate (CK) and phosphorous levels. Many of these clinical conditions are not reversible.98

Chickens fed diets with increased rancidity parameters (peroxide and aldehyde concentrations) experienced increased mortality from fatty liver syndrome (FLS). Total blood proteins of affected chickens were elevated, as were lipoproteins and total lipids.28

HANDLING AND STORAGE

Wild birds naturally feed on an array of fresh foods while their captive counterparts are provided with foods that have been stored for extended periods. Nutritionally imbalanced food supplies are not uncommon in wild situations. Agriculture produces seeds and nuts only at the end of the growing season, usually in the fall. Storage increases the potential for nutrient degradation. Nitrogen flushing and storage under refrigeration are steps that discourage oxidation.

COLD DARK STORAGE HELPS PREVENT RANCIDITY

Storing walnuts in the light at 21° C resulted in profound oxidative changes.51 However, walnuts stored in the dark at 5° C for 25 weeks, even in 50% oxygen, were without a trace of rancid taste.⁵¹ However, it should be remembered that rancidity, as determined by chemical analysis, precedes taste detection.

Storing corn oil at room temperature for 48 months resulted in rancid oil, whereas storage in the refrigerator did not.16 A specific strain of mice fed the rancid corn oil showed significantly increased expression of oncogenes in all major organs. The results demonstrated that rancid oils, rich in n-6 polyunsaturated fatty acids, could initiate tumors and promote tumor growth.86

COOKING

In the preparation of a formulated diet, cooking (roasting, pelletizing or extrusion) is designed to stabilize oils. However, depending on the condition of the products being mixed, some combinations may cause flash rancidity (D. Jones, personal communication 2000). This is due to the presence of enzymes in items like grains and peanuts that cause natural fermentation when exposed to warm moist air. The lipase concentration in some grains is very high. Oats and brown rice are examples. 43b Dehulling and milling these products causes rapid deterioration (rancidity) unless they are heat stabilized prior to storage or further processing. When these raw products are combined under the heat of processing, this flash rancidity can occur. For this reason, these ingredients need to be roasted or other wise partially cooked separately, then mixed with the other ingredients prior to final processing.

Raw soybeans contain trypsin inhibitors and can therefore be difficult to digest. This enzyme is a critical part of digestion in monogastric animals. Trypsin inhibitors are inactivated by heat.14b,70b Cooking also improves the availability of methionine and cysteine.14b Overcooking destroys or makes unavailable certain amino acids (lysine) and greatly reduces natural vitamin precursors such as tocopherols and carotenoids.

MOISTURE CONTENT

Lowering the moisture content of a product also acts as a stabilizer. Moisture plays a vital chemical role in most oxidation processes. 43b Levels below 5% are often required to deter degradation. The author (GIH) has shown that these low moisture levels cause minor proventricular irritation evidenced by excessive regurgitation and minor weight loss in some pet umbrella cockatoos. Even at these low moisture levels, over time nonfree 'water' is all lipases need to act. Non-free water cannot be removed by drying.43b

PACKAGING

Many bird foods are packaged in plastic, cellophane, coated paper or cardboard boxes. The latter two prevent exposure to light. Airtight containers (plastic, cellophane) prevent moisture from evaporating, but many do not stop oxygen from crossing into the food. The oxygen then breaks down essential nutrients or changes their biological activity. An advertised vitamin A content of 12,500 IU/kg may be reduced to as few as 1,500 IU/kg by inadequate packaging, with further deterioration once the package is opened. Even if one starts with a nutritionally sound, preservative-free formulated diet, the lack of proper packaging and resulting rancidity cancel its effectiveness.

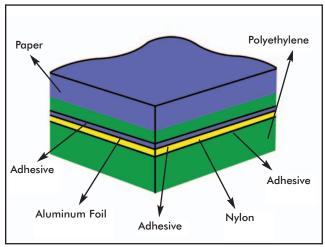

Fig 4.2.1 | Quadruple laminate packaging helps preserve the freshness of fomulate diets and prevents rancidity.

Fig 4.2.2 | A red-lored Amazon fed a seed and table food diet has an overgrown maxillary rhamphotheca that has been recently honed down to a more normal shape.

Fig 4.2.3a | A green-winged macaw fed a seed and table food diet. The red feathers are almost pink. Black pigment is co-mingled with green. The beak is hyperkeratotic. The breast and wing feathers are tattered and picked.

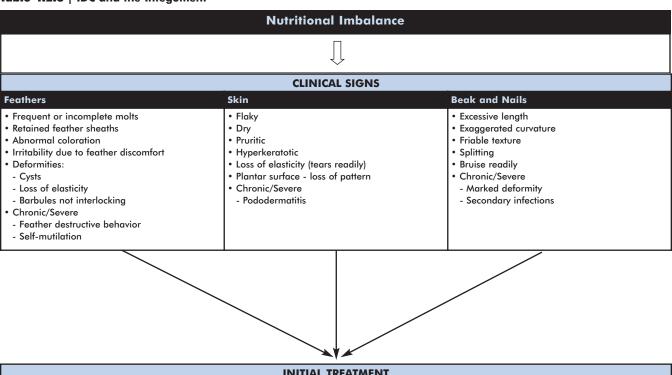

Fig 4.2.3b | A yellow-naped Amazon fed a seed and table food diet. The bird is obese, the maxillary rhamphotheca is overgrown and the feathers are abnormally pale green. The rectrices are tattered. Structural abnormalities make the coverts of the wing and body contour feathers lack the homogeneous interlocking appearance of a normal bird.

To avoid oxygen deterioration, chemical preservatives like ethoxyquin (originally used to soften rubber, later as a herbicide) and propylene glycol have been used for decades in dry animal foods. They have not been deemed safe for human foods. Recent public demand for more natural pet foods has led to a variety of newer techniques to avoid rancidity.

Lipid peroxidation can particularly affect products composed of organic ingredients that lack synthetic preservatives but is no less an issue for any products that are inadequately packaged.

For these reasons, all foods need to be smelled when first opened. If they smell like old frying grease or linseed oil they are rancid. A taste test should be observed when first offering a new bag of food to the bird. If the bird acts hungry but rejects the food it might be rancid. Rancid foods should not be fed. Following the manufacture's directions for handling the food and shelf life will usually prevent rancidity problems.

INITIAL TREATMENT				
Husbandry	Medical	Procedural	Diet Conversion	
Increase UVB Increase outdoor exposure: Humidity Ventilation Sunlight Psychological stimulation Improve available perches, increased variety of sizes and textures Increase exercise, both physical and mental Verify or improve hygiene	Antipruritics: Systemic Topical Treat secondary infection if present and significant Psychotropic medications if selfmutilating Parenteral vitamin supplementation for severe deficiencies Blood work and other diagnostics if indicated	aging for pododermatitis when	Evaluate for the following: Essential amino acids Balanced fat and CHO Vitamins at physiologic levels (not excessive or deficient) Free of dyes and preservatives Need for supplemental essential fatty acids Formulated diet is often most convenient and effective Monitor weight during conversion	

EVALUATION OF THERAPY

- Dietary conversion is necessary for long-term treatment and control.
- Anticipate exacerbation of clinical signs for 3-9 months (pruritus, flaking of skin and molting) with integumentary regeneration.
- If clinical signs worsen, perform diagnostic work-up for systemic sequelae to IDC.
- At 9-12 months, marked improvement should be noted in initial clinical signs.

There are few natural oxidative inhibitors. Tocopherols (vitamin E) and rosemary leaves have been tried. In the author's experience, preliminary studies of products containing rosemary had less than ideal acceptance, and the test subjects' had lower than desired body weights.

The natural antioxidants found in whole cereal grains have not been fully exploited.

The development of quadruple laminate bags (Fig 4.2.1), consisting of a layer of poly-coated extruded paper

(blocking light), a layer of nylon for puncture resistance, a metal alloy as a barrier to oxygen and a polyethylene layer to resist changes in moisture and retain oils, have increased shell life of non-synthetically preserved products by up to 14 months. However, once the seal is broken and exposure to oxygen and moisture increases, these products are only viable for up to six weeks before clinical signs produced in birds resemble those of birds maintained on diets depicted in Figs 4.2.2-4.2.3a,b. It is important that clients adhere to the manufacturers'

Fig 4.2.4 | A blue and gold macaw that was fed a diet of pasta, crackers, cookies, pellets and vegetables. The feathers are tattered and lack symmetry. The blue feathers contain a black pigment. Under the contour body feathers, the bird had an excessive number of pinfeathers.

Shelf Life	Use within 4-6 weeks of opening*	
Storage	Store in manufacturer's packaging only if adequate**	
	Express air to minimize oxidation	
Feeding Frequency	Offer fresh food 2-3 times daily dependent on species	
Feeding Amount	Ensure bird eats all food offered, including crumbs. Amount fed should maintain normal body weight.	
Selective Feeding	Don't allow bird to favor individual particles	
Supplementation	Follow manufacturer's instructions as to types and amounts of supplementary foods	
Water	Don't allow birds to dunk food in water as this degrades vitamins and pollutes water leading to bacterial and fungal overgrowth	

^{*}Diets composed of nonorganic ingredients may have a longer shelf life due to synthetic preservatives

storage directions, as even nutritionally adequate diets have a limited shelf life once opened (see Table 4.2.4).

The IDC from a Systemic **Point of View**

Although birds seldom present with only one system affected by improper diet cascade, diagnosis, treatment and prevention are best discussed by looking at a single system at a time.

Early recognition by the clinician of the effects of IDC on various systems allows diagnosis and implementation of dietary therapy. This is a key element in avian preventive health care.

Fig 4.2.5 | This blue and gold macaw hen died after laying a clutch of 5 infertile eggs. Note the pinfeathers after all the body and extremity feathers were removed. Also note the black pigment in the normally blue feathers. The bird had been fed a seed and table food diet.

INTEGUMENTARY SYSTEM

The integument is the site where clinical signs of dietary inadequacy often appear to be noticed first, but these early stages are so commonly encountered that they may not be perceived as abnormal (Table 4.2.3). The stratified squamous epithelial (SSE) cells characteristic of skin are involved in the production of integumentary components such as the nails, beak, feathers, and feather follicles. In addition to the integument, SSE cells are found in the rhinal cavity, mouth, salivary duct junctions, tear ducts, ear canal, syrinx, air sac junctions to the lungs, bile duct, pancreatic duct, cloaca, renal tubules and vagina. Nutritional imbalance can influence the structure and function of any of these sites. While nutritional inadequacies are most often manifested in the integument, the clinical presentation can be complicated by more serious underlying illnesses. The development of nutritionally balanced formulated diets has dramatically reduced the incidence of dermal disorders, but such diets are far from successful in totally eliminating these problems once they have developed.

The Physical Exam Form outlined in Chapter 6, Maximizing Information from the Physical Examination, is a useful tool for identifying signs and common clinical presentations listed in Table 4.2.3. Minor integumentary signs are often overlooked by the bird care industry. It is important to establish a program of wellness with regular checkups, especially for new birds, to identify problems with nutritional inadequacies at an early stage.

KERATINIZATION

Hyperkeratosis is characterized by failure of the new cells to differentiate beyond the squamous stage.

^{**}Many products are packaged in inferior packaging resulting in breakdown of key nutrients before packaging is even opened. Quadruple laminate packaging preserves nutrients for extended periods of time.

Table 4.2.5 | IDC and the Digestive System

	TREA	ATMENT	·
Diagnostics for Secondary Infections	Medical Treatment	Environmental Concerns	Dietary Conversion
Endoscopy and organ biopsy Culture and sensitivity Radiology Hematology Biochemistry Ultrasound	Fluids Systemic treatment of secondary infections Gl stimulants Bacteria, enzyme replacement Lactulose Milk thistle SAMe Apple cider vinegar Chronic Ultra clear®f Hepasan®e	Proper humidity	Same as Table 4.2.3 Formulated diet is often most con venient and effective

Dysfunctional, excessively keratinized cells replace normal cells. This can result in epithelial lesions and an increased susceptibility to infection. If the imbalance is severe and prolonged, columnar epithelium undergoes metaplasia to SSE. Keratinization can result in a loss of function of the tissues involved, including those of the alimentary, reproductive, respiratory and urinary tracts.

Clinical signs of hyperkeratosis involving the integumentary system can manifest as overgrowth of the beak and nails, which retain their outer covering due to a proliferation of basal cells. The keratinized outer coatings of pinfeathers are thicker, less flexible and retained much longer than normal. Retained coatings prevent pinfeathers from opening and such feathers appear to be painful to the birds if the unopened feathers are manipulated. Clients commonly report that birds with chronically retained pin feathers are irritable and vocalize as if in pain during preening (Figs 4.2.4 and 4.2.5).

While hyperkeratosis is generally associated with dietary deficiencies of vitamin A, excesses of vitamin A are also correlated with hyperkeratosis. The percent of squamous cells present in nasal flushes has been used as an indicator of vitamin A toxicosis.⁵⁸ It is important to obtain a full dietary history before prescribing vitamin A

supplementation to treat hyperkeratosis. In rodents, oral supplementation with vitamin A failed to raise serum vitamin A levels in the absence of adequate vitamin E.⁶ Therefore a mixture of both vitamin E and vitamin A may be required to treat hyperkeratosis due to a vitamin A deficiency. Deficiencies of zinc and biotin have been associated with hyperkeratosis. Biotin deficiencies, which can result from excess of salt, are correlated with hyperkeratosis on the footpad and the plantar surfaces of the toes.⁷ Thus the caveat to not treat all hyperkeratosis with vitamin A injections is valid.

GASTROINTESTINAL SYSTEM

Secondary to the dermal system (and some behavioral traits), the avian clinician is likely to observe gastrointestinal tract (GIT) dysfunction next in the unfolding of the IDC (Table 4.2.5). Vitamin A deficiency may interfere with normal growth, rate by influencing functionality of the small intestine by altering the proliferation and maturation of cells of the intestinal mucosa. ¹⁰⁴ Hyperproliferation of enterocytes, decreased number of goblet cells, decreased alkaline phosphatase activity, and decreased expression of brush-border enzymes are all correlated with vitamin A deficiencies. ¹⁰⁴

HPC3 = Samples collected from same birds after 12 weeks on HPC

The Fecal Gram's Stain in Psittacines

While early studies of captive birds indicate that they commonly have low levels of gram-negative bacteria in cultures of feces, 5,9,18,21,54,99 other researchers maintain that autochthonous flora in healthy parrots are not gram-negative. 37,38,45,46,47,102 Normal fecal flora of psittacines is comprised of 100% gram-positive, nonspore forming rods and cocci.37,38,45,46,47,102 One study of wild yellow-naped Amazon chicks showed 60% of cloacal cultures had Enterobacteriacea.99 The author (GJH) has hypothesized that this group of nesting birds were under undue stress from poachers, the presence of humans guarding the nests and a declining natural environment. For 20 years, this author (GJH) has used fecal Gram's stains to evaluate the normal flora of pet birds. 46 Studies of wild psittacines in a recent trial confirm the absence of gram-negative bacteria. 45.47 Gram-negative bacteria were reduced to almost zero after conversion of African grey parrots from a typical seed-based diet to a nutritionally balanced one.¹⁰² (Fig 4.2.6) Glunder found (E. coli or Klebsiella spp.) it nearly impossible to colonize in the intestine of budgerigars on nutritionally balanced diets.38 Joyner54 whose MPVM thesis study looked at breeding pairs of aviary budgerigars on a seed-based diet, reported a 60% cloacal presence of gram-negative rods, and reported this as normal. This may be considered normal for a seed-eating budgerigar in this study, but it should not be considered normal for a healthy bird on a balanced diet.

Normal resident microflora maintains an acidic environment that inhibits the proliferation of gram-negative rods and yeast. An imbalance in the intestinal homeostasis results in alterations to the normal populations of microflora, and thus the distribution of bacteria in the

Table 4.2.6 | Techniques for Performing a Fecal Gram's stain

- 1. Fecal samples should ideally be collected at home and refrigerated until evaluated to prevent the proliferation of saprophytic gram-negative bacteria that may be interpreted as pathogenic.
- 2. A small amount of feces should be applied to a precleaned glass slide using the wooden end of a cottontipped applicator. The sample should be spread into a uniform, thin, even film, using a single swath.
- 3. Heat fix
- 4. Place slide on staining tray:
 - Apply 3 drops of gentian violet to the sample and allow to stand for 30 seconds (stains all bacteria blue).
 - · Rinse with water and drain excess water.
 - · Apply 3 drops of Gram's iodine and allow to stand for 30 seconds (closes pores on gram-positive bacteria).
 - Apply 5 drops 95% ethyl alcohol to decolorize blue stain from gram-negative bacteria.
 - Rinse immediately with water and then add 5 drops saffron to stain gram-negative bacteria red.
 - · Rinse immediately with water and blot dry with lens paper or tissue.
- 5. Scan slide under low microscope power for suitable evaluation site.
 - Using the oil immersion lens, scan several fields for a further idea of uniformity.
 - · Choose a uniform field and begin to estimate the total number of bacteria, i.e., count 10 bacteria, assess the proportion of entire field occupied by those 10 bacteria and then estimate the total bacterial population per 1000x field.
- 6. Record results (see Table 4.2.7)
- 7. The presence of gram-negative cocci indicates improper staining technique.

With experience, the entire process should take less than 2-3 minutes to perform.

GIT. Normal intestinal flora of parrots, seen as gram-positive (blue) bacteria on a fecal Gram's stain, represent both aerobic and anaerobic bacteria such as *Bacillus*, *Corynebacterium*, *Streptomyces*, *Lactobacillus*, *Streptococcus* and *Enterococcus* spp.,³⁷ some of which are not able to be cultured using standard techniques.

Enterobacteriaceae are gram-negative (red) bacteria that include pathogens (eg, Salmonella spp., E. coli, Acinetobacter spp.) and non-pathogenic species. Enterobacteriaceae are not normal components of unstressed parrots' microflora³⁷ and are not detected in preliminary studies of wild parrots. 45,47 However, normal flora bacteria can become secondary pathogens depending on the functional state of the host defense system.³⁷ Systemic disease, including septicemia and death, can occur when bacteria leave the mucosal surface and penetrate the intestinal wall, a situation that can be precipitated by an imbalanced diet influencing the integrity of mucosal surfaces. Parrot-specific Lactobacillus^g (currently only available in Europe) has been used successfully to treat chronic coliform infections, eliminating the incidence of E. coli on culture.37 Techniques for performing and recording a fecal Gram's stain are outlined in Tables 4.2.6 and 4.2.7.

The fecal Gram's stain is an important component of complete patient evaluation of psittacines. Although not definitive in making a diagnosis, it provides a visual screen of the proportions of bacteria present in the GIT at the time of sampling. When interpreted in conjunction with a complete physical exam and diet history, it can determine the next diagnostic step: whether to proceed to a culture and aggressive therapy or to treat conservatively with husbandry changes.

Interpreting a Fecal Gram's Stain

Ideally, one should use a fecal Gram's stain in conjunction with culture and antibiotic sensitivity testing and only then, antibiotic therapy. Figs 4.2.7-4.2.22 represent a range of fecal Gram's stains commonly seen in clinical practice (1000x oil immersion field) from psittacines maintained predominantly on seed-based diets. Figs 4.2.23-4.2.27 are representative of wild Australian psittacines taken from birds in the December breeding season when diets include a number of wild blossoms (D. Brennan, personal communication). A healthy psittacine should have a predominance of gram-positive rods and cocci, with an absence of gram-negative rods.

Malnutrition and liver disease are characterized by changes in the number and distribution of bacteria on the fecal Gram's stain. In the early stages, the change is reflected by:

• Decrease in total bacteria

- Decrease in percentage of gram-positive cocci
- Increase in % gram-positive rods

In the later stages of malnutrition and liver disease, the Gram's stain generally shows:

- Increase in presence of gram-negative rods (generally speaking, the more gram-negative rods, the more pathologic the situation)
- Presence of yeast which are judged as to their clinical significance by the number of budding yeast per field.
 The greater the percentage of budding yeast found, the more likely that the immune system is compromised.

The fecal Gram's stain of the stool from pet passerines should be free of bacteria, yeast and *Macrorhabdus* sp. organisms.

Clostridia (gram-positive, anaerobic organisms), are commonly associated with fetid stools in both cockatoos with cloacal prolapse and macaws with cloacal papillomas. Both the clostridial organism and the underlying cause require treatment¹⁰⁶ (Figs 4.2.16 and 4.2.18).

Hepatobiliary System

Fatty Liver Syndrome

The following discussion is offered because the author (GJH) believes fatty liver hemorrhagic syndrome (FLHS) of poultry is similar to a common clinical disease in psittacines, which is primarily a result of malnutrition.⁷¹ FLS, generally a consequence of an imbalance in energy metabolism, is associated with an accumulation of excessive abdominal and hepatic fat. Lipid infiltration weakens the hepatic cellular structure and results in hepatomegaly. Lipid deposits are also found in some skeletal muscles, alimentary tract, autonomic ganglia, CNS, pineal gland, kidney, heart and occasionally, small amounts are seen in the corneas, exocrine pancreas, adrenal medulla and epithelium of the thyroid follicles. Endogenous hypercholesterolemia and cessation of egg production are characteristic signs of a similar disorder in poultry, fatty liver hemorrhagic syndrome (FLHS). 100

The numerous blood vessels of an enlarged friable liver are easily ruptured during egg laying. The rupture of large blood vessels can result in death. This disease (FLHS) is most often seen in apparently healthy poultry in a high state of egg production. It also affects young birds, especially chicks from young parents, with 50% higher mortality in females than males. Fatty liver syndrome is especially evident in older, overweight pet birds that are fed a diet of seeds or nuts, but can be seen in handfed chicks as well. Trauma associated with adult birds falling from a perch or being held for a routine clinical examination has caused hepatic rupture in FLS

Figs 4.2.7-4.2.12 | Fecal Gram's Stains (FGS) Commonly Observed in Psittacines in Clinical Practice (oil immersion 1000x).

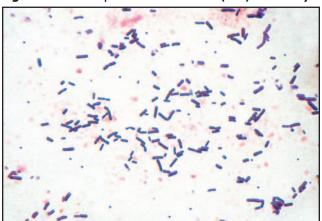

Fig 4.2.7 | Budgerigar, 4-year-old male: Hx = Apparently healthy bird, fed organic formulated diet.^b Normal flora. Clinical Signs (CS) = none. FGS = Normal distribution of organisms: 157 total bacteria per field, 70% gram-positive rods, 30% gram-positive cocci, 0 gram-negative bacteria, 0 yeast. Digestion of food is complete.

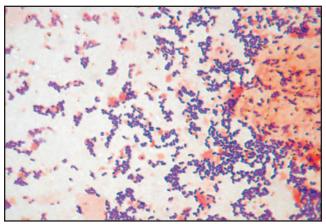

Fig 4.2.9 | African grey parrot, 4 years old, sex unknown: Hx = Intermittent vomiting or loose stool, not as playful. FGS = 400 bacteria per oil field, 95% gram-positive short rods, 5% gram-positive rods, 0 yeast. Overgrowth of intestinal bacteria, enterotoxemia, malnutrition. Rx = Aggressive, dietary change, antibiotics and supportive care.

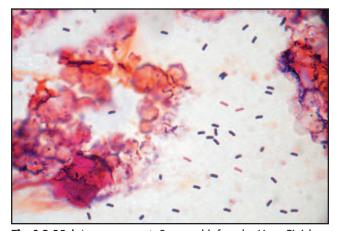

Fig 4.2.11 | Amazon parrot, 8-year-old, female: Hx = Finicky eater, occasionally grumpy. CS = Failure to molt correctly, balding of feet, obvious layering of beak, overgrowth of nails, minor feather-picking. FGS = 40 bacteria per field, 90% gram-positive rods, 0% gram-positive cocci, 10% gram-negative rods. (The normal binding of urates by protein is occasionally seen in fecal gram's stains). Rx = Conservative diet change.

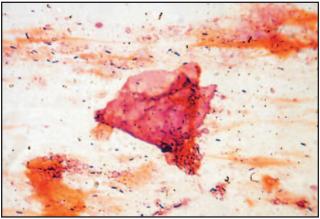

Fig 4.2.8 | Cockatiel, 14-year-old male: Hx = Bird presented for boarding, seed diet. CS = Dull feather color, retained pin feathers. FGS = 55 bacteria per field; 90% gram-positive rods, 10% gram-positive cocci. Hyperkeratotic cell with characteristic straight sides suggests intestinal microflora imbalance, probably due to malnutrition, early liver disease. Rx = Conservative, diet change.

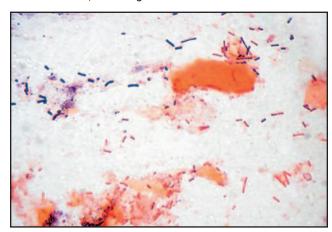

Fig 4.2.10 | Psittacine: latrogenic gram-negative rods due to staining error. An error is suspected when the demarcation of gram-positive and -negative is streaked and the groups are similar in shape and size, differing only in color. Note the presence of a normal intestinal epithelial cell, which is rounded and takes on a blue color. Compare this to the straight, pointed edges of the hyperkeratotic cell in Fig 4.2.8. Rx = None.

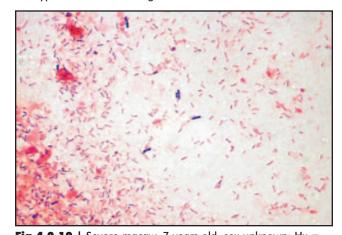

Fig 4.2.12 | Severe macaw, 7 years old, sex unknown: Hx = Depressed, not eating, weak. CS = Underweight, scant feces, dark yellow urine and urates, malcolored feathers. FGS = 200 bacteria per field, 1% gram-positive rods, 0% gram-positive cocci, 98% gram-negative rods. Rx = Aggressive for enteritis and septicemia.

Figs 4.2.13-4.2.18 | Fecal Gram's Stains Commonly Observed in Psittacines in Clinical Practice (oil immersion 1000x).

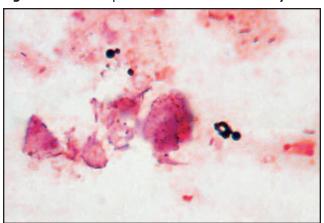

Fig 4.2.13 | Meyer's parrot, 6 years old, sex unknown: Hx = Diet of seeds and supplements, treated previously for "bacteria." CS = Depressed, fluffed, poor appetite. FGS = Scant bacteria, two budding yeast organisms, suggesting early malnutrition. Rx = Aggressive, antimicrobials, dietary change and supportive care.

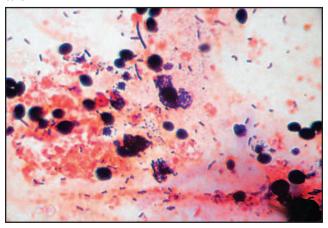

Fig 4.2.15 | Cockatiel, 8-year-old female: FGS = 80 bacteria per field, 80% gram-positive rods, 20% gram-positive cocci; 20 non-budding, yeast-like structures (possibly from bakery products in diet, not clinically significant). Rx = None.

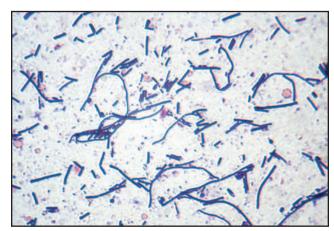

Fig 4.2.17 | Budgerigar, 4-year-old male: CS = Digestive upset. FGS = 200 bacteria per field, 5% gram-positive cocci, 95% gram-positive rods, of which half are large filamentous rods. Rx = Aggressive. See Chapter 30, Implications of *Macrorhabdus* in Clinical Disorders.

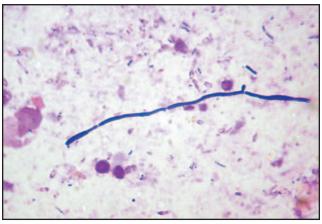

Fig 4.2.14 | Ring-necked parakeet, 9-year-old male: FGS = Scant gram-positive bacteria, occasional gram-negative, many apparent bacterial forms and colors; invasive filament of yeast budding bi-directionally. Rx = Aggressive, antimicrobials, supportive care, dietary correction.

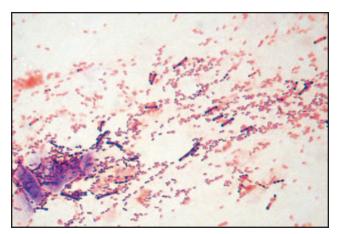

Fig 4.2.16 | Umbrella cockatoo, 6-year-old female: Hx = Exposure to carnivorous pets, seed only diet. CS = Fetid stool, weight loss, passing undigested food. FGS = 200 bacteria per field, 10% gram-positive rods of which 45% are *Clostridium* spp., 45% gram-negative rods. Rx = Aggressive antimicrobials, supportive care, dietary correction.

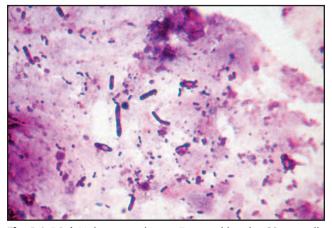

Fig 4.2.18 | Moluccan cockatoo, 7-year-old male: CS = smelly stool. FGS = 50 bacteria per field, 90% gram-positive rods, 10% gram-positive cocci, 30 *Clostridium* spp. organisms. Rx = Aggressive (see Fig 4.2.16).

Figs 4.2.19-4.2.22 | Fecal Gram's Stains Commonly Observed in Psittacines in Clinical Practice (oil immersion 1000X).

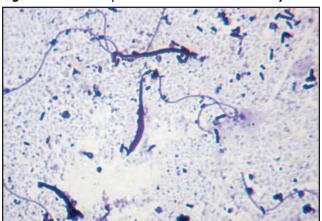

Fig 4.2.19 | Budgerigar, 3-year-old male: Hx = Frequent masturbation. FGS = Presence of sperm. Rx = None.

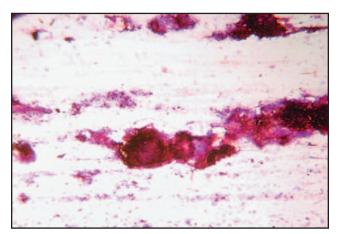

Fig 4.2.21 | Psittacine: FGS = Large amounts undigested fiber (low microscopic power).

Fig 4.2.20 | Psittacine: Various forms of gastrointestinal diseases can be suspected if digestion of fiber or dietary ingredients is improper. Top slide = Normal fiber content of feces. Bottom slide = Undigested fiber.

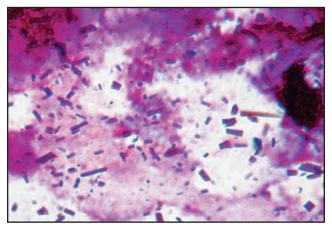

Fig 4.2.22 | Psittacine: FGS = 20 bacteria per field, 100% gram-positive rods, lots of undigested food particles cluttering field, suggesting some form of gastrointestinal disturbance.

Figs 4.2.23-4.2.27 | Fecal Samples from Free-ranging Australian Psittacines (oil immersion 1000x).

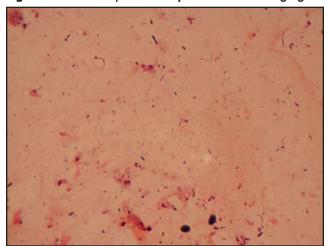

Fig 4.2.23 | Eolophus roseicapillus: 30 bacteria/field, 50% small to medium gram-positive rods, 50% gram-positive cocci, no gram-negative rods, no yeast, slight debris, digested particles, two yeast-like forms.

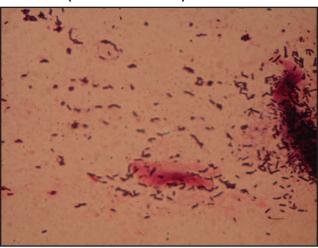

Fig 4.2.24 | Eolophus roseicapillus: 170 bacteria/field, 90% large gram-positive rods, 10% gram-positive cocci, no gramnegative rods, no yeast, moderate debris, digested particles.

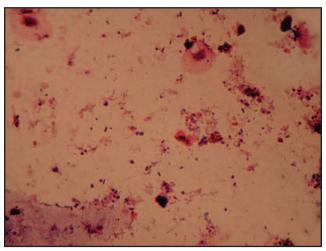

Fig 4.2.25 | Cacatua tenuirostris: 60 bacteria/field, 60% small to medium gram-positive rods, 40% gram-positive cocci, no gram-negative rods, no yeast, moderate amount debris, digested particles, two circular non-cornified cells with nucleus, one pollen-like form.

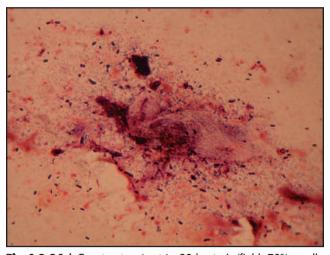

Fig 4.2.26 | Cacatua tenuirostris: 90 bacteria/field, 70% small to medium gram-positive rods, 30% gram-positive cocci, no gram-negative rods, no yeast, abundant debris (some not digested).

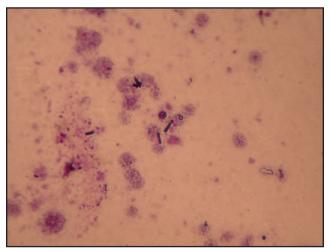

Fig 4.2.27 | Cacatua tenuirostris: 15 bacteria/field, 50% large gram-positive rods, 50% gram-positive cocci, no gram-negative rods, no yeast, moderate amount debris (cellular and digested particles).

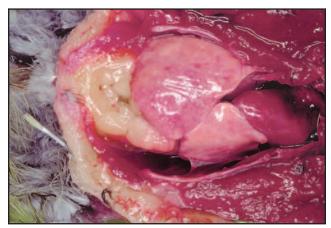

Fig 4.2.28a | Fatty liver in a Mexican red-headed Amazon. The bird died while being restrained for grooming. The serum was lipemic. The veterinarian never realized long nails and beak were a sign of a problem.

Fig 4.2.29 | Fatty liver in a baby cockatiel fed a commercial handrearing formula containing excessive fat.

birds. A fatty, swollen liver that compromises the abdominal and caudal thoracic air sacs can result in death from hypoxia (Figs 4.2.28a,b). Although there are some hereditary tendencies towards the disease, nutrition plays a major role in its development. There is little data on FLS in caged birds and a plethora of references on FLHS (Fig 4.2.29). Because FLHS is on the decline in poultry as a result of such data, we offer the following discussion for consideration.

Enzymatic Function and FLHS

A number of plasma enzymes increase with FLHS, such as AST, LDH and glutamate dehydrogenase (GDH). These can be used as indices of the syndrome in laying hens²⁷ (Table 4.2.8).

Signs and Symptoms

An overweight bird with a marked accumulation of fat is a likely candidate for hepatic lipidosis. Typically these birds may be considered behaviorally normal. Early signs include bile pigments in the urine, changes in the fecal Gram's stain and abnormal feather coloring. See Chapter 15, Evaluating and Treating the Liver for a further discussion.

Fig 4.2.28b | The feces from an obese bird will on occasion have a red cream-colored urate after restraint. The renal vessel fragility is a strong prognostic indicator of fatty liver disease.

Table 4.2.8 | Enzymatic Changes in Fatty Liver Affected Birds. 10,11,105

Enzyme	FLHS-affected birds	
Acetylcholinesterase	↑ activity	
Aspartate aminotransferase	↑ activity	
Aspartate transaminase	↑ activity	
Glucokinase	↓ activity	
Gluconeogenesis	↓ activity	
Lactate dehydrogenase	↑ activity	
Phosphofructokinase	↓ activity	
Sorbitol dehydrogenase	↓ activity	

Nutritional Implications for Development of FLHS

Dietary Fat

Liver fat and excess body weight (associated mainly with an accumulation of abdominal fat) are believed to be two predisposing factors contributing to the onset of FLHS in poultry. 42 Unnecessarily force-feeding birds can increase liver fat and plasma estradiol, producing FLHS. 11,42 A similar condition has also been observed in cockatoos and cockatiels fed improperly formulated diets (Fig 4.2.29). However, high liver lipid content alone may not be sufficient to cause FLS, as adequate dietary levels of lipid trigger a feed-back mechanism, enhanced by dietary starches, to prevent hepatic lipid accumulation. 43a Long chain fatty acids, especially those of the n-3 family are beneficial in the diet as a preventative measure.44 Ground flaxseed (100 g/kg), flaxseed oil (40 g/kg) significantly decrease hepatic fat.95 Safflower phospholipids decrease liver triglycerides (hepatic triglycerides increase with liver hemorrhage score84), serum cholesterol and body weight.³ Palm kernel oil at 2% of dry matter weight of diet decreases FLS.76 Palm oil is rich in vitamin E and carotenoids. The vitamin E fraction (400 mg/kg) is in an approximate ratio of 30:70 tocopherols:tocotrienols.

Tocotrienols have an unsaturated side chain rather than the saturated chain of the more common tocopherols. Tocotrienols more effectively lower cholesterol and show stronger antioxidant activity than tocopherols. See earlier discussion under Rancidity for oxidation's possible role in FLHS in poultry.

L-cysteine

Deficiencies in essential amino acids can increase mortality from FLHS and may be prevented with supplementation of L-cysteine at 6 g/kg of feed.26 N-acetyl-L-cysteine (NAC) is the pre-crystallized form of the simple amino acid cysteine. It is a powerful antioxidant and immune support substance that neutralizes the free radicals produced by normal metabolic activity. While both cysteine and methionine are precursors of glutathione, NAC is more effective. During digestion, approximately 85% of the sulfur groups of L-cysteine are lost (these contribute to the active portions of glutathione), while only 15% are lost from NAC, resulting in up to six times more sulfur groups after digestion (for detoxification). NAC is also a better source of glutathione than supplementation with glutathione itself, because less than half the supplemental glutathione leaves the digestive system for other organs. This greater efficiency is important since cellular glutathione levels tend to drop 30 to 35% with age.

S-adenosylmethionine (SAMe)

S-adenosylmethionine (SAMe), a natural metabolite of the amino acid methionine, was discovered as a pharmaceutical in Italy in the 1970s and has been available in Europe for over 20 years. It is the most active of all methyl donors arising from the amino acid methionine. While healthy livers synthesize sufficient methionine, liver disease can impair SAMe syntheses. On a cellular level SAMe maintains mitochondrial function, prevents DNA mutations and, restores cellular membrane fluidity so that cell receptors become better able to bind hormones and other factors.

SAMe's methyl groups make possible the production of the "fat burner" carnitine; the neuro nutrient acetyl L-carnitine; the primary ATP energy reservoir, creatine phosphate; the stress hormone and neurotransmitter, adrenaline; the neuro nutrient and chief membrane phospholipid, phosphatidyl choline; and the DNA bases methyl adenine and methylcytosine.

In addition to transmethylation, SAMe is involved in transsulfuration, which begins with the by-products of the transmethylation of S-adenosylhomocysteine (SAH). SAH yields homocysteine, which can be converted to cysteine and then to a family of key sulphur biochemicals: glutathione, glutathione peroxidase, glutathione-S-transferase and taurine. As much as 80% of dietary cysteine, low in many foods, can lose its bioactive

sulfhydryl groups passing through the stomach. The glutathione compounds and taurine play important roles in liver detoxification.

SAMe production decreases with age. Dietary supplementation may be required for older birds prone to fatty liver disease. Without SAMe, the liver protective glutathione cannot be synthesized. While increasing glutathione levels through supplementation is desirable, glutathione alone is not a substitute for the combined actions of SAMe and glutathione.

Betaine and SAMe

Anhydrous betaine (trimethyl glycine, not to be confused with the digestive aid betaine hydrochloride), is a substance made from beet sugar that increases SAMe levels. Impairment of SAMe synthetase may result in SAMe being manufactured through the betaine pathway, an alternative to the SAMe synthetase-dependent methion-ine-plus-ATP route. Increasing levels of betaine reduce fatty infiltration and provide the precursors for the free radical scavenger glutathione.

It is recommended that SAMe supplementation in humans for a diet comprising 16% protein range between 100 to 500 mg, with higher requirements in females. Mild stomach irritation may result if not using a product with an enteric coating. There have been no clinical trials on the effectiveness of SAMe for birds with liver disease. Early empirical data is encouraging.

Vitamins and SAMe

Once a SAMe molecule loses its methyl group it breaks down to form homocysteine. On its own homocysteine can be extremely toxic, but the presence of vitamins B_6 , B_{12} and folic acid convert homocysteine into glutathione or re-methylate it into methionine. Deficiencies of any of the active coenzyme forms of vitamins B_2 , B_6 , B_{12} or folic acid will disrupt SAMe production. Reciprocally, diminished SAMe production will impair conversion of folic acid and B_{12} to their coenzyme forms.

In order to maximize the effectiveness of the interlocking SAMe pathways, the addition of the water-soluble vitamins B_2 (20 to 200 mg), B_6 (40 to 400 mg), B_{12} (0.5 to 5.0 mg) and folic acid (0.8 to 2.0 mg) is required. Vitamins B_6 , B_{12} and folic acid also convert the toxic homocysteine to glutathione or re-methylate it into methionine.

Biotin

While low dietary protein predisposes chicks to develop FLHS, high dietary protein can cause classical signs of biotin deficiency.¹¹ Biotin is an essential coenzyme involved in the conversion of protein to carbohydrate and the conversion of protein and carbohydrate to fat.

Biotin enzymes are important in protein synthesis, amino acid deamination, purine synthesis, and nucleic acid metabolism. Biotin itself is required for trans-carboxylation in the degradation of various amino acids; it also plays an important role in maintaining normal blood glucose levels when dietary intake of carbohydrate is low. Biotin deficiency is most severe in young chicks of heavier strain and greater rate of weight gain;8 promoting higher growth rates in psittacines may predispose birds to FLS.

Many of the problems associated with biotin deficiencies and FLHS result from biotin's role as a cofactor for many enzymes. These include: a decreased rate of lipogenesis; depressed gluconeogenesis from lactate and glycerol; an increase in the activities of fatty acid synthase (FAS), citrate cleavage enzyme (CCE) and phosphokinase¹¹; abnormal fatty acid composition of infiltrated lipid, with an increased proportion of monounsaturated fatty acids; severe hypoglycemia; and depleted hepatic glycogen. 105 Low fat or protein levels that increase the metabolic rate of biotin-dependent enzymes (pyruvate, acetyl CoA carboxylase) aggravate the condition. Biotin also serves as part of the prosthetic group, a transient carrier of CO₂, and is required for normal long-chain unsaturated fatty acid synthesis and is important for essential fatty acid metabolism.⁵⁹ FLHS is generally worsened by a high proportion of long chain saturated fatty acids.48

Biotin deficiencies can result from a dietary deficiency of biotin or other factors that impact on the stability of biotin. The richest sources of biotin include: royal jelly, liver, kidney, yeast, blackstrap molasses, peanuts and eggs, while poor sources include: corn, wheat, other cereals, meat and fish. However, the chemical form of biotin (bound or unbound) as well as its overall content in feed is important, as less than one-half of the biotin in various feeds is biologically available. Starvation of birds can lower liver biotin levels, leading to an increase in liver weight and lipid content.10 The addition of raw egg white also decreases biotin availability as the proteinaceous avidin binds very tightly to biotin. While low mortality is seen in broilers fed freeze-dried egg white at 11.8 g/kg, mortality is high if dietary concentrations exceed 17.7 g/kg.

Not all forms of biotin are equivalent in their action; biotin contains three asymmetric carbonations, with eight different isomers. Only the isomer d-biotin contains vitamin activity; the stereoisomer l-biotin is inactive.⁵⁹ Biotin is inactivated by rancid fats and choline ⁹⁷ and gradually destroyed by ultraviolet radiation. Structurally related analogues of biotin can vary in activity from anti-biotin activity, to no activity, to partial replacement.7 Oxybiotin has 1/3 biotin activity for chicks whereas desthiobiotin and biotin sulfate are inhibitory to bacteria. Biotinidase, present in pancreatic juice and intestinal mucosa, releases biotin from biocytin during the luminal phase of proteolysis. Physiological concentrations of biotin are absorbed from the intestinal tract by a sodium-dependent active transport process, which is inhibited by desthiobiotin and biocytin.92

Cecal microorganisms do not supply chickens with significant amounts of biotin; they compete with the host animal for dietary biotin, thereby increasing the requirement. In poultry, polyunsaturated fatty acids, ascorbic acid, and B vitamins may influence the demand for biotin. Biotin is rapidly destroyed as feeds become rancid, with 96% inactivation occurring in as little as 12 hours if linoleic acid of a high peroxide number is added to the diet. Supplementary choline in biotin-deficient diets decreases biotin status in chicks and increases mortality from FLHS.¹⁰⁵ The use of sulfa drugs can also induce a deficiency. Conversely, α -tocopherol decreases inactivation of biotin.

Minimum biotin requirements have been established for a number of commercial species, with higher requirements for turkeys compared to chickens (NRC, 1994). The minimum dietary requirements of 120 μg/kg dietary dry matter determined for poultry increases to 160 μg/kg in order to prevent fatty liver development and as high as 240 µg/kg when sunflower seed meal is a dietary component.75 Incorporation of 2% palm kernel oil can reduce the prophylactic dietary biotin requirements down to 120 μg/kg.⁷⁶

Choline

Choline plays an essential role in fat metabolism in the liver. Choline prevents abnormal accumulation of fat by promoting fat's transport as lecithin or by increasing the utilization of fatty acids in the liver itself. While conversion to betaine is required before choline can be a methyl donor, betaine itself fails to prevent FLHS. The addition of choline can decrease the amount of fat in the liver. Diets high in fat exacerbate choline deficiencies, thus increasing the dietary requirement. This is particularly important for chicks, as they are unable to synthesize choline until approximately 13 weeks of age.⁶⁸ However, mortality increases in chickens that are supplemented with B vitamins (other than biotin), with higher mortality if choline is also supplemented. 105 Only 57% of biotin in multivitamin premixes⁶⁸ is retained if the supplement contains choline.

Normal dietary choline requirements for poultry range from 800 to 2,000 mg/kg. Choline is largely absent in fruit and vegetables and is low in corn. Wheat, barley and oats have higher levels of choline. Peanuts are a good source of choline as are cereal germs, legumes and

oilseed meals. Choline needs of poultry fed wheat-based diets are much lower than those fed on other grains. Wheat and sugar beets are high in betaine, which can spare choline for some reactions.

Vitamin E

Vitamin E powerfully combats the peroxidation of polyunsaturated fatty acids in the liver. Daily supplementation of 100 to 400 IU Vitamin E in conjunction with low dietary vitamin A is recommended for birds suffering from FLHS. See earlier discussion of rancidity for possible role of fat-soluble vitamin destruction and FLHS.

Silymarin (Milk Thistle)

Silymarin is a collective group of polyphenolic flavanolignans extracted from the seeds of the milk thistle (Silybum marianum). The flavanoids are powerful antioxidants that increase levels of glutathione and protect the liver from oxidative damage. They may promote growth of new, healthy liver cells.^{32,85} While clinical trials in birds have not been undertaken to evaluate the effectiveness of silymarin, it has proven effective empirically when administered twice daily to birds with liver disorders. See Chapter 10, Integrative Therapies, Chapter 9, Therapeutic Agents and Chapter 15, Evaluating and Treating the Liver for further information.

Environmental Influences

While nutritional imbalances are the main factors contributing to both FLS and FLHS, stress alone can initiate FLHS. When birds are subjected to mild stress and/or short-term fasting, liver glycogen reserves become rapidly depleted and a progressive hypoglycemia develops that can prove fatal. Stress-associated lipogenesis increases cholesterol synthesis and converts excess glucose to fatty acids, which are stored as triglycerides.

Pesticides

While pesticide levels of individual ingredients may be deemed safe, a combination of a variety of pesticides or an accumulation of pesticides in tissues can result in pesticide toxicity. Polychlorinated biphenyls (PCBs) increase liver and body weights of birds associated with FLHS and can increase total cholesterol¹⁰³. Many pesticides have estrogenic actions; high estrogen levels are associated with FLHS.⁴² These estrogenic pesticides mimic the action of normal endogenous hormones and influence ovarian function. A combination of estrogen

and excess dietary energy create sufficient fat deposition in the liver for FLHS to occur.⁸⁹

Summary of Fatty Liver Disease

A variety of nutritional factors are implicated in the development of FLS and FLHS in chickens, but many are avoidable by providing a nutritionally balanced diet. Some factors are exacerbated by other dietary ingredients, environmental stimuli or infectious diseases. While the name of the disease, fatty liver (hemorrhagic) syndrome, implicates dietary fat levels as causative factors, there are many other dietary components that are important and warrant further consideration. We feel this model may serve the captive parrot industry well, as empirically the same corrections seem to apply.

IRON STORAGE DISEASE

Iron storage disease (ISD) is prevalent in many frugivorous and insectivorous birds maintained on commercially formulated foods (Table 4.2.9). Iron storage disease differs from one of its precursors⁵³, hemosiderosis, which is defined as the excessive accumulation of iron (hemosiderin) in hepatocytes or in free circulation in the blood, without alteration of normal tissue morphology or damage to any of the major organs. Various factors have been implicated in the development of this disease, including genetic predisposition, immunological stress, nutritional inadequacy and viruses; dietary iron content has been the main focus of nutritional investigations. The causative factors of ISD have been addressed by several authors. 29,36,70a Further studies on the interactions of dietary sugars, copper and iron metabolism have been proposed.87 The discussion here will be confined to nutritional implications in the development of ISD. There is a high correlation with commercially formulated foods and ISD. Table 4.2.10 highlights a number of avian families in which the disease has been reported.

While iron is essential for fundamental cell functions, it is also a catalyst for chemical reactions involving free radical formation that can lead to oxidative stress and cell damage. Uptake of iron from the diet is regulated in the intestine, so acute intoxication is not observed under natural conditions. Cellular iron levels are generally regulated to maintain adequate substrate levels while minimizing the pool of potentially toxic 'free iron.' The main control of body iron homeostasis is in the duodenum where dietary iron is absorbed, but no controlled means of eliminating unwanted iron has evolved in animals. Consequently, chronic ingestion of large amounts of absorbable iron can lead to the storage of iron in the liver in many species.

Iron storage disease results from the accumulation of

iron in various tissues, with the liver most frequently involved. In severe cases, iron pigment is found in the liver, spleen, gut wall, kidney and heart; this leads to subsequent development of ascites, heart failure and multisystem pathology.²⁵ Iron may be found within the Kupffer cells in the liver³⁶ and the macrophage cells of the spleen, especially where concurrent diseases, such as hemolytic anemia, septicemia, neoplasia or starvation, are present.²⁵

The syndrome of excessive iron overload in mynahs shares most of the important histopathologic characteristics with idiopathic hemochromatosis in human beings. Iron storage disease has been correlated with immunological stress,25,36 as well as crowded conditions.53 Reduced peristalsis or neuropathic gastric dilatation may increase iron absorption.36 Stress increases lipid peroxidation and diminishes vitamin E levels, resulting in a lower level of antioxidant activity. Iron and vitamin E are involved in electron transfer in reduction/oxidation cycles; a dietary surplus of either iron or vitamin A decreases the α -tocopherol concentration. Therefore, any impact on vitamin E levels may reduce the protection of biological membranes against oxidation. In addition, diets high in saturated fats increase iron absorption.79

Nutritional Implications for ISD

Highly frugivorous or highly insectivorous birds have adapted to foods low in iron (fruits and insects). The high vitamin C content of many fruits enhances iron uptake from iron deficient diets. Consequently, high dietary iron has been implicated in the development of the disease and it is generally recommended that iron content of commercial diets be maintained below 100 mg/kg⁵³, and in mynahs 19 to 25 mg/kg.^{29,94} However, birds have been maintained on commercial foods that reflect the high values of iron in some dietary components of wild toucans⁷⁸ (150 mg/kg) with no evidence of iron storage disease. Diet is not implicated in the development of ISD in the Rothschild mynah.

Vitamin A and Iron Uptake

Some commercially formulated products have high vitamin A content (see Chapter 4, Nutritional Considerations, Section I Nutrition and Dietary Supplementation). These high vitamin A levels are in contrast to the low vitamin A content of fruits and insects. Vitamin A from plants arises from conversion of carotenoids, a regulated process that avoids potential vitamin A toxicity. Productivity of psittacines increases when birds are transferred to formulated diets low in vitamin A but high in carotenoids. ⁶⁷ Additional vitamin A is either supplied from plant based carotenoids in the diet or else it may

Recurrent or chronic respiratory infections are common with chronic IDC and marked changes in the respiratory epithelium.

be inferred that birds have an overall low requirement for vitamin A. The incidence of ISD is negligible in these

Low serum retinol is associated with mild anemia in adult humans.30 Retinol also plays a role in increasing levels of hemoglobin in children, especially those on iron supplementation.^{2,63} Dietary iron also influences conversion of ß-carotene to retinol by enhancing ßcarotene 15,15'-dioxygenase activity in the small intestinal mucosa of rats.31 High levels of dietary vitamin A may negatively influence availability of other fat-soluble vitamins such as vitamin E.

In contrast to vitamin A, the presence of carotenoids in microsomal membranes partially inhibits the loss of α -tocopherol, especially during the late phase of oxidative stress when ß-carotene decreases phospholipid hydroperoxide production.⁷³ However, despite its beneficial antioxidant activity, ß-carotene, like vitamin A, can increase the absorption of iron by preventing the inhibitory effect of phytate and tannins on iron absorption by forming complexes with iron that maintain solubility in the intestinal lumen.62

The antioxidant activity of the different carotenoids is variable. The inhibitory effect of ß-carotene on the production of lipid peroxidases is less than that of the extremely potent antioxidant astaxanthin from marine micro algae. Astaxanthin protects the mitochondria from

damage by Fe++-catalyzed lipid peroxidation during vitamin E deficiencies. 62 It is two-fold more effective than ßcarotene in inhibiting production of lipid peroxidases.39 Peridinin, another carotenoid of marine micro algae, limits oxidative damage on iron-liposomes, possibly by decreasing membrane permeability to initiators. 12 While the direct benefits of the blue-green algae Spirulina platensis have not been evaluated in birds, the phycobilins (phycocyanins and allophycocyanin) of S. platensis act as potent free-radical scavengers (hydroxyl and peroxyl) and inhibit microsomal lipid peroxidation in humans.88 Dietsb, low in vitamin A and containing micro algae, have demonstrated improvements in health and productivity of large psittacines.⁶⁷

Canthaxanthin is a carotenoid compound that is supplemented to promote feather pigmentation in flamingos and scarlet ibis. A recent study suggests that canthaxanthin can substantially alter the antioxidant status of murine liver tissue in vivo. In mice, canthaxanthin reduces both cellular content of lipophilic antioxidants and the activity of enzymatic antioxidants, as well as increasing iron concentrations in the liver by up to 27%. ISD has been diagnosed in flamingos.20 The addition of canthaxanthin to the diets of these birds may alter the protective ability of tissues against oxidative stress in vivo and increase iron storage in the liver. The carotenoid canthaxanthin is associated with eye and liver damage in humans.

Table 4.2.12 | IDC in Geriatric Budgeriagar with Goiter

History	Clinical Signs	Treatment
• Diet Seed based	Regurgitation Crop mucus accumulation Dyspnea Swollen thyroid	Dexamethasone (if severe) Iodine Diet change

Summary of ISD

While diets low in iron are advocated for birds susceptible to ISD, the high vitamin A content of commercially formulated foods may also be implicated in the development of the disease. It is recommended that diets low in iron, vitamin A and saturated fats be presented to birds susceptible to this disease in addition to supplementation with vitamin E. Furthermore, high levels of dietary ß-carotene may be detrimental. Vitamin A activity should be provided from other carotenoid sources, especially those present in blue-green algae, such as Spirulina platensis. Frugivorous species should be provided with fruits low in vitamin C to minimize uptake of iron from commercial diets. Recent recommendations on the use of tannins from tea to tie up iron have shown promise. It is evident that further research on this topic is required.

RESPIRATORY SYSTEM

Loss of function of epithelial tissue is a problem in the respiratory system because loss of cilia and mucus production decreases cleaning capacity (Table 4.2.11). In chronic cases, serum oozes from endothelial ulcerations and provides a culture media for bacteria, yeast or other fungi (Figs 4.2.30-4.2.31). The nares can reflect the internal condition.

Liths that roll up to form "balls" can develop from desquamated epithelial cells when proper cleaning function has not been maintained. These balls may randomly accumulate in such places as the connection between

the cul-de-sacs of the infraorbital sinus or the layering of the rhinal cavity under the operculum. In the case of the sinus, they may act as one-way valves causing the cervicocephalic air sac to hyperinflate. In the rhinal cavity, the accumulation leads to rhinitis or rhinorrhea (often containing blood). The liths in the bronchial syrinx area or the air sac junction to the lungs can become secondarily infected with yeast or other fungal spores (Fig 4.2.31). Recent reports from Europe indicate this is a common respiratory sign seen in African greys with circovirus.

Liths are not confined to the respiratory tract. They can accumulate in the bile duct. When flecks of liths partially obstruct the duct in cockatiels, the duct balloons to resemble a gall bladder. Liths in the kidney are often associated with gout. In the uterus, they can form egglike structures of various sizes and shapes.

BUDGERIGAR GOITER

It has been common knowledge since the 1950s, that budgerigars (Melopsittacus undulatus) develop goiter on a seed diet low in iodine. Table 4.2.12 shows the typical scenario. The bird may only show obesity. Most common clinical presentations are "vomiting" (regurgitation) of a thick liquid (mucus) that accumulates on the feathers of the head. Respiratory sounds (squeaking) from impingement on the syrinx by the swollen thyroid are also a frequent complaint. While diagnostic tests are possible, they are seldom used due to their expense and the ease of diagnosis using response to treatment. Dexamethasone may speed the response to injectable

iodine by decreasing thyroid swelling and may be life saving in severely dyspneic birds. Complete recovery is insured by adding iodine to the water or seeds. Since other deficiencies will soon manifest on such a diet, only geriatric birds and birds that refuse to convert to formulated diets are treated by iodine supplementation alone.

INGLUVITIS

Baby psittacines from parents on seed-based diets commonly are plagued by ingluvitis. Seed-based malnutrition is the primary cause and can be prevented with formulated diets. Secondary invaders (yeast and Enterobacteriaceae) may require specific antimicrobials and resemble liver and gastrointestinal disorders caused by the same agents. In these latter conditions, crop atony followed by ileus is not unusual, especially in cockatiels. These birds are very difficult to cure and frequently suffer a prolonged wasting type malaise. See Chapter 7, Emergency and Critical Care and Chapter 14, Evaluating and Treating the Gastrointestinal System, for further discussion.

RENAL DISEASE

Excesses of dietary protein and the accumulation of waste products derived from the catabolism of protein result in uric acidemia and to a lesser degree, uremia, in birds. Excessive dietary protein is catabolized to uric acid and other nitrogenous compounds normally excreted by the kidneys. Decreased renal function leads to accumulation of these compounds. One goal of nutritional therapy is to achieve nitrogen balance by proportionally decreasing protein intake as renal function declines, except in cases of protein losing nephropathy.

Gout is associated with the deposition of a white chalky substance (urate) on body organs (visceral), in joints (articular) or in ureters (renal). Urates are the end products of protein metabolism in birds. Their accumulation impairs the function of key organs and can eventually be fatal. While excess dietary protein has been implicated in the increase of serum uric acid, birds are usually able to excrete excesses. ⁵⁸ However, fasting, dehydration or a diet deficient in lysine may increase serum uric acid. Alterations to normal elimination of uric acid, which can

cause extensive renal damage, have also been associated with vitamin A deficiency leading to gout.⁵⁸

Dietary lipids have been implicated in the progression of chronic renal disease, especially in relation to a change in the balance of renal prostaglandins. A diet rich in arachidonic acid leads to a predominance of PGE₂, prostacyclin and thromboxane A₂ (TBXA₂), resulting in a shift toward greater vasodilatation and less platelet aggregation (Table 4.2.13). For further discussion on this topic, see Chapter 16, Evaluating and Treating the Kidneys. The effects of excess vitamin A and/or D are discussed in Section I of this chapter.

CARDIOVASCULAR DISEASE

Atherosclerosis

Atherosclerosis is problematic for psittacines in captivity⁵² that are provided with high-fat diets and little exercise compared to their free-ranging counterparts. Atherosclerosis involves the deposition of cholesterol within the innermost lining of the arteries and subsequent inflammatory response and fibrosis. While cholesterol-lowering agents and dietary changes are treatment mainstays in humans, the development of the disease may be prevented in birds with nutritionally balanced diets containing antioxidants.

Damage to the endothelial lining of the internal surfaces of the heart increases permeability to lipoproteins and macrophages. Increased endothelial permeability leads to the accumulation of lipoproteins within the subendothelial space, which initiates the formation of atherosclerotic plaques. The oxidation of lipoproteins retained within the subendothelial space is responsible for the inflammatory response seen in atherosclerosis. Lipoprotein oxidation is a necessary step in the development of atherosclerotic plaques; the oxidation of lowdensity lipoprotein (LDL) is implicated in lesion formation in the aorta. Vitamin A can attenuate the oxidation of LDL and consequently minimize or even reverse aortic plaque development and endothelial dysfunction.

Oxidants are produced by the normal metabolic functions of the endothelium, macrophages, and smooth muscle of the arterial wall. Lipoproteins that accumulate within the subendothelial space are exposed to these cellular oxidants. Although a small degree of lipoprotein oxidation may occur during circulation, most lipoprotein oxidation occurs within the arterial wall. It is therefore noteworthy that lipoproteins are themselves enriched with antioxidants such as vitamin E, coenzyme Q_{10} (ubiquinone) and carotenoids. Water-soluble antioxidants found in the plasma, such as vitamin C, may also be important in preventing oxidation of lipoproteins in the circulation.

In a recent abbreviated study, two high fat and two low fat diets were fed for periods of 24, 28 and 32 days. Results showed that palm kernel oil (derived from the seed) produced significantly higher levels of plasma cholesterol and phospholipid concentrations than did sunflower oil. No conclusions on the effect on atherosclerosis could be drawn. The authors had previously shown 84% sudanophilic staining levels in aortas of parrots presented for necropsy. The authors recommended diets of up to 10% fat on a dry matter basis.

Nutritional Supplementation for the Treatment of Atherosclerosis

In studies on humans, palm oil (derived from the fruity coating outside the seed), which is distinct from palm kernel oil, has proven beneficial in the treatment of atherogenesis. Palm oil is very rich in carotenes, vitamin E and coenzyme Q_{10} . The cholesterol lowering action of palm oil is attributed to its high vitamin E content, especially the tocotrienol fraction. A typical palm oil vitamin E concentrate contains up to 30% α -tocopherol and 70% mixture of different tocotrienol isomers (20% α -tocotrienol, 20% γ -tocotrienol, 40% α -tocotrienol, 10% δ -tocotrienol and 10% others).

Cardiomyopathy

Cardiomyopathy has been associated with a number of disease entities including malnutrition, as the pathogenesis in birds is similar to mammals, it is possible that similar nutritional inadequacies are implicated. While supplementation levels have not been established for birds, studies of mammals indicate that supplementation with taurine, vitamin B_6 , coenzyme Q_{10} and carnitine are helpful.

Taurine

Taurine is an essential amino acid in cats as they have a limited ability to synthesize taurine from cysteine and methionine. Because there are many physiological similarities between carnivorous birds and felines, it is possible that taurine deficiency is implicated in the development of cardiomyopathy in carnivorous birds, especially those provided with commercial dog foods that are typically low in taurine. Plasma taurine concentrations can be influenced by food intake and food deprivation. Whole blood concentration is a more reliable index of taurine status, as this only declines after prolonged periods of depletion. While taurine levels for cats (plasma <20 to 30 nmol/ml; whole blood <150 nmol/ml) are indicative of dietary deficiencies, similar data is not available for carnivorous birds.

Vitamin B_e

Mild deficiencies in vitamin B₆ can interfere with taurine conversion. The heat treatment associated with the pro-

duction of commercial pet foods degrades B6.

Coenzyme Q_{10} (Co Q_{10})

Coenzyme Q_{10} is an antioxidant that plays a role in mitochondrial function. A deficiency of CoQ_{10} is correlated with deterioration in heart function. CoQ_{10} is similar in structure to vitamin K and can interfere with the blood-clotting mechanism. Studies with humans indicate that supplementation at 2 mg/kg body weight reduces symptoms associated with cardiomyopathy and heart failure. $\$ blockers and cholesterol-lowering drugs from the statin family can interfere with the body's production of CoQ_{10} .

Carnitine

Carnitine is a small, water-soluble, vitamin-like quaternary amine found in high concentrations in mammalian heart and skeletal myocytes. L-carnitine is synthesized primarily in the liver from the amino acids lysine and methionine. Long-chain fatty acids are important for maintaining a constant energy supply to the heart. Carnitine is a critical component of the mitochondrial membrane enzymes that transport activated fatty acids. In addition to its role in fatty acid transport, free carnitine serves as a mitochondrial-detoxifying agent. Because of the high-energy requirements of the heart muscle, it is particularly vulnerable to carnitine deficiencies. A recent report shows the potential for L-carnitine to reduce the percent body weight and lipoma size in budgerigars. 14c

OPHTHALMIC DISORDERS

Cataracts

While causative factors have not been identified clearly, cataracts have been described in aging macaws.24 Nuclear cataracts associated with aging occur in the center of the lens. The nucleus of the lens is particularly sensitive to nutrient deficiencies. Nuclear cataracts are associated with deficiencies in the fat-soluble vitamins A and α -tocopherol and the water-soluble vitamins B, (riboflavin) and B₃ (niacin). Carotenoids have potent antioxidant activity with marginal inverse associations between the carotenoids lutein and cryptoxanthine and the development of nuclear cataracts. Riboflavin is important in the production of glutathione peroxidase; deficiencies in glutathione peroxidase have been correlated with cataracts. Selenium and vitamins C and E are also helpful in preserving glutathione levels. However, supplementation with selenium is not recommended as cataracts have been correlated with both deficiencies and excesses of this trace mineral. Taurine deficiency (particularly in animals fed heat-processed diets) has also been correlated with cataracts.

Table 4.2.14 | The IDC and the Reproductive System

History	Signalment	Diagnosis	Treatment
Diet Seeds, nuts, produce, supplemental vitamins, table foods	Eggs No eggs, small clutches, soft/rough-shelled eggs, infertile eggs Hatchlings Failure to hatch, (need assistance), early neonatal death, bent legs/beaks, crop/digestive disorders, require hand raising (from day 1) Adults Egg binding, masturbation, regurgitation, nest building, mate mutilation	Blood Increased cholesterol, hyperlipidemia Diet Change Response takes up to a year Reproductive Tissue Ulture uterus, biopsy uterus/testis, endoscopy (cystic ovaries) Eggs Necropsy, culture	Treat specific disorder Diet Nutritionally balanced formulated organic foods, limit supplements: low sugar produce Breeding Birds: 5-10% high fat items (sunflowers seeds, nuts) sugary fruits & vegetable (necessary for breeding stimulation) Genetics Cockatiels Choose birds that are not chronic egg layers Deplete body stores of nutrients Hormone therapy Salpingohysterectomy

The cortical cataract occurs in the cortex of the lens and a subcapsular cataract starts as opacity under the capsule, usually at the back of the lens. The prevalence of cortical cataracts is reduced in the presence of polyunsaturated fatty acids. Insufficient n-3 fatty acids or excess saturated or 'trans' (hydrogenated) fats may impact on the progression of eye disease. While high levels of α -tocopherol reduce the risk of nuclear opacity, medium levels are associated with a reduced risk of cortical opacities.

Macular Degeneration

While macular degeneration has not been reported in birds, there are different kinds of macular problems. In other animals the most common is age-related macular degeneration. Zinc deficiencies can exist in older birds from poor absorption from food. Zinc is highly concentrated in the eye, particularly in the retina and tissues surrounding the macula. Zinc is necessary for the action of over 100 enzymes, including chemical reactions in the retina. While zinc supplementation may be beneficial if there is a dietary deficiency or malabsorption problem, excess zinc may also interfere with other trace minerals such as copper. The xanthophylls lutein and zeaxanthin selectively accumulate in the macula, providing what is known as the macular pigment. Singlet oxygen production in the eye can be increased by UV light exposure, but this is yet to be established in birds. It is assumed this increased oxidative damage is due to increased free radicals in the retina. Lutein and zeaxanthin are scavengers of these free radicals. Anti-oxidants (vitamin A, C and E) may also help slow down macular degeneration and other aging factors associated with activated oxygen from exposure to light, but this has yet to be established.

REPRODUCTIVE SYSTEM

Various reproductive problems can be caused by a nutritionally imbalanced diet (Table 4.2.14). A high fat and sugar based diet is strongly suspected to be involved in the overly stimulated breeding bird. See Chapter 3, Concepts in Behavior, Section III Pubescent and Adult

Psittacine Behavior for a table of foods hypothesized to be stimulatory.

Protein and Amino Acids

Amino acid requirements increase at least one week prior to the first oviposition for growth of the oviduct and accretion of egg proteins. While overall protein requirements for birds laying small clutches may be little more than maintenance requirements, a deficiency in essential amino acids may increase overall protein requirements. Budgerigars maintained on seed-based diets that provided only half the lysine, methionine and cysteine required, produced fewer hatchlings, fledglings, fertile eggs, and total eggs.4

Vitamins

Fat-soluble vitamins can influence breeding potential; a reduction in vitamin A and E reduces antioxidant function and increases exposure of lipid-rich tissues to peroxidation. Both deficiencies and excesses of Vitamin A influence epithelial integrity. The resulting hyperkeratosis can influence mucin production as well as proper tone and elasticity of reproductive tissue. Vitamin A deficiencies can result in failure of spermatogenesis, decreased size of testes and decreased sexual activity in males.

Dietary excesses of vitamin A may negatively influence reproductive output of birds. Improved productivity has been recorded in a variety of larger psittacines maintained on diets low in vitamin A and high in vitamin E.67 A study of blue and gold macaws (Ara ararauna) highlights the importance of maintaining breeding birds year round on nutritionally balanced diets. Productivity significantly decreased when birds were transferred to seed-based diets during the nonbreeding season.⁶⁷ Maternal diets can influence nutrient transfer to embryos, as well as the antioxidant status of the developing embryo and hatchlings.

Table 4.2.15 | Action of Pesticides at a Cellular Level

Action	Result	Pesticide
Altered membrane integrity	Interferes with fluid and electrolyte movement	DDT Pyrethrins
Altered cell volume regulation	Alters energy metabolism, reducing energy availability to drive active transport systems, synthesis of macromolecules and main- tenance of osmotic balance	Dinitrophenol Chlorophenol fungicides Arsenates Tin fungicides
Results from metabolic defects	Abnormal accumulation of lipids and pigments	industrial estrogenic wastes
Alteration of protein synthesis	Denaturation or inactiva- tion of enzymes	Oxalic acid Fluoroacetate Organophosphates Carbamates
Disturbance of growth regulation	DNA damage that is not properly repaired or exceeds homeostatic control	Damage documented but not the cause

Lipids

While obesity can be detrimental to breeding birds, an imbalance of essential fatty acids is also problematic. Linoleic acid (n-6) typically reduces liver fat and improves egg production. 42,43a It is preferentially retained by laying hens. Conversely, high levels of linolenic acid reduce egg production in laying hens.1

Typical fatty acid profiles of chicken spermatozoa display considerable resistance to manipulation by dietary means.⁵⁶ Dietary supplementation of docosahexaenoic acid (DHA) may inhibit synthesis of n-6 fatty acids in the testes23 resulting in an accumulation of DHA, a concurrent decrease in vitamin E concentrations, and increased susceptibility to lipid peroxidation. While supplementation with n-3 fatty acids may be beneficial for the treatment of inflammatory diseases (see Chapter 16, Evaluating and Treating the Kidney), it may influence fertility by impacting the integrity of the component fatty acids in the spermatozoa's phospholipid membranes.

Sperm output generally decreases with age, but this decrease can be prevented by supplementing diets with oils rich in either arachidonic acid or DHA, in conjunction with vitamin E (200 mg/kg). Testes mass can also be increased up to 1.5 times in aging birds when supplemented with essential fatty acids. However, supplementation with linoleic acid in the absence of vitamin E can result in 50% reduction in spermatozoa per ejaculate in aging birds.

The cloaca can transmit microbes retrograde into the reproductive tract. The hypothesis that there is a passage of beneficial microbes at the time of copulation is intriguing. It has been hypothesized that females copulate with multiple males to gain microfloral advantage for the offspring from flora transmitted at copulation.⁶⁴ The female is thought to benefit by protection from future as well as present infections that become overwhelmed by the inoculum.⁶⁴ This is another area that, if proven, shows the value of the microflora to the body.

ADVERSE FOOD REACTIONS

Food Allergies

The bird should undergo a complete physical examination including appropriate diagnostics to look for any underlying pathology, which may be exacerbated by or in addition to the suspected food allergy. Not all dermal problems are related to nutritionally imbalanced diets as some birds, like cats and dogs, have allergic reactions to certain dietary ingredients. Advanced stages often result in feather picking and self-mutilation. While early signs of these food allergies are yet to be described, failure of nutritional therapy may warrant skin allergy testing and/or a simplified organic dieta where ingredients such as corn and sunflower seeds are eliminated. While these ingredients have been incriminated in the development of dermal disorders⁶⁵, they are regularly included in both formulated and homemade diets as primary ingredients with no reports of digestive disorders. Organic formulated diets are free from pesticide residues and preservatives that could be potentially allergenic. Common allergens for mammals (wheat, gluten, egg and dairy products) should also be eliminated from sensitive birds, although no proof exists they are a problem. A commercial organic mash dieta is composed of the following ingredients: buckwheat, hulled gray millet, hulled white (proso) millet, spirulina, chia, alfalfa, clay, sea kelp, anise, natural sources of vitamins, minerals and trace minerals. (Can be wrapped in thin slices of banana for feeding). This mash has been clinically correlated with the abatement of pruritis in several birds suspected to be suffering from food allergies. Once the mash has been accepted, the proportion of banana can be gradually decreased until eliminated. However, a bird could potentially be allergic to any dietary ingredient.

DIETARY ANTIFEEDANTS AND **XENOBIOTICS**

As the practice of organic farming diminishes the detrimental impact of pesticides on wildlife and their habitats, the consumption of organic products minimizes the need for animals in captivity to modify and detoxify antifeedants in their diet. Evaluating the potential burden that residual pesticides in non-organic ingredients place on a bird requires understanding the biochemical complexities of detoxification mechanisms that enable animals to process these potentially harmful chemicals. This can apply equally to foodstuffs with high concentrations of antifeedants, such as alkaloids, cardiac glycosides and phenolic compounds, that require detoxification. However, pesticide tolerance has not been evaluated in

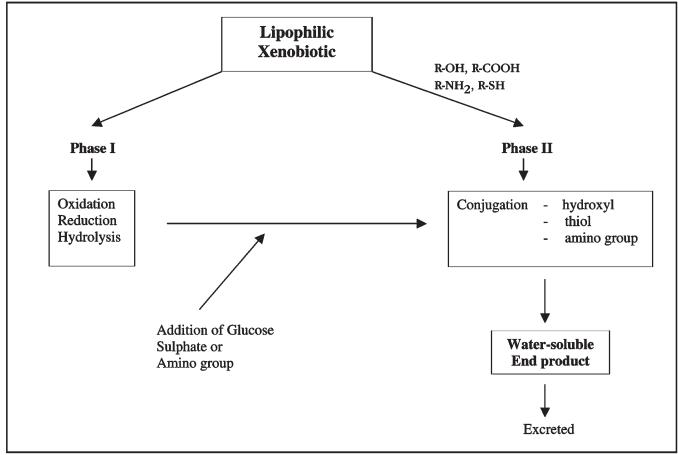

Fig 4.2.32 | Phase I and II detoxification of xenobiotics.

companion birds. Clinically significant improvements in health and productivity have been reported for birds maintained on organic diets.⁶⁷

Actions of Chemical Contaminants

Most toxicological injury results in cellular damage. The toxic response to any specific chemical is the result of dysfunction of relatively few basic biologic processes. Normal processes can be suppressed or stopped completely, or they can be enhanced beyond normal physiologic limits and, in turn, affect other systems dependent on their controlled functions. Cellular responses to chemical toxins occur through both structural and metabolic mechanisms in the cell. A single response or a number of actions can be elicited from an individual pesticide (Table 4.2.15).

Detoxification of Xenobiotics

Xenobiotics are pharmacologically, endocrinologically, or toxicologically active substances not endogenously produced and therefore foreign to an organism. Pesticides acting as estrogens (xenoestrogens) are a common subject of discussion at wild bird disease seminars^{33,34,40,41,103} (Fig 4.2.32).

The detoxification of xenobiotics is a biphasic process

carried out by a suite of non-specific microsomal enzymes referred to as mixed function oxidases (MFOs) that act primarily in the endoplasmic reticulum. The detoxification process converts a lipophilic compound into a highly water-soluble product that is suitable for excretion in urine or feces. The two phases of detoxification place different demands on nutrient stores in the body. Therefore, the ability to digest and process foreign chemicals may vary from one individual to another, depending on species, feeding ecology, gender and developmental stage. If liver function is diminished from any other disease process, detoxification capability may also be affected.

Nutritional Requirements for Detoxification

Dietary nutritional deficiencies, such as minerals (calcium, copper, iron, magnesium, zinc), vitamins (E, C and the B complex) and proteins, can limit the chemicals necessary for the synthesis of enzymes or conjugating agents. Energy deficits induced by fasting decrease the activity of xenobiotic metabolizing enzymes. Protein malnutrition may also impair enzyme synthesis, MFO activity and hepatic glutathione concentration.

Detoxification may also have an impact on ascorbic acid (vitamin C) levels, as glucuronate is a precursor in the

Table 4.2.16 | Behavioral Traits Attributed to Nutritional Inadequacy

History	Signalment Individualistic	Treatment
Overly permissive owners	Distrustful	Formulated Diet
Behavior	Obsessive/Compulsive	Nutritionally balanced
•Craves sweets/fats	Depressed, Separation Anxiety	Environment
Diet	Reproductive	Adjust, move/redecorate cage
Poorly balanced 30-60%	Masturbation, hiding, nest building, egg laying	Medication
warm table foods and numerous treats	Feather Picking, Mutilation	Human chorionic gonadotropin
Seed based	Biting, Screaming	Lupron, dexamethasone
Husbandry	Sweet/Lovable Clinging	Behavior
• Poor	Aggression	Modification, tolerance training, exercise
		-

biosynthesis of ascorbate in most animals. Deficiencies of ascorbate reduce the ability to detoxify foreign chemicals. Stress may also increase the rate of ascorbate metabolism. Any changes in environmental attributes (structural or nutritional) may impact on levels of ascorbate and thus a species' ability to detoxify antifeedants in its diet.

By consuming several different plant foods, and so using various rate-limiting detoxification pathways, an animal can ingest larger amounts of food per unit time enabling them to obtain more energy and nutrients. While varying the diet may be beneficial to some animals, there is the risk of exposure to a greater variety of biologically active compounds. If more than one xenobiotic is absorbed there can be an additive, synergistic or antagonistic interaction between them. Therefore, the ability to utilize a single food substrate or to incorporate various plant species into the diet will be based on the individual.

Implications for Pesticide Residues in Avian Diets

Birds maintained in captivity are confronted with a different set of stresses than their wild counterparts. In addition to adjusting to the stress of being maintained in a confined environment, they are generally supplied with foods that have been domesticated for the human palate or formulated foods composed of foreign ingredients. There are various natural antifeedants in foods that the avian system must detoxify, and the addition of residual pesticides in non-organic foods adds to this burden. Tannins differ in their actions. Condensed tannins have the potential to bind to proteins, rendering them insoluble and unavailable for assimilation; hydrolysable tannins do not bind to proteins, but require detoxification, placing a drain on nutrients associated with the detoxification system. A nutritionally balanced diet is still not optimal if levels of feed contaminants require extensive detoxification.

The toxicity of certain pesticides may be underestimated, as cumulative effects or delayed toxicity can occur long after exposure. This confuses the interpretation of signs credited to pesticide exposure. Synergistic effects may also be observed, if one chemical affects the solubility, binding, metabolism or excretion of another. Therefore,

while studies on the effects of individual pesticides may not indicate any detrimental actions, a combination of two or more pesticides may enhance toxic actions. Potentiation occurs when one chemical enhances the toxicity of another, even though the toxicity of the potentiator is minor or nonexistent. See Chapter 11, Low-risk Pest Management for actions one might consider in avoiding pesticides.

Pesticides and Behavioral Abnormalities

Levels of pesticide contamination in bird foods composed of non-organic ingredients have yet to be evaluated. Behavioral abnormalities associated with pesticide exposure include: reduction in courtship behavior^{33,34,74}, reluctance of females to take food from males, changes of activity patterns in males40, reduced levels of nest defense^{33,34,41}, alterations of incubation behavior, decreased parental attentiveness resulting in increased embryonic mortality^{33,41,82}, decreased time feeding young, fewer sorties to feed young and increased time away from nests.33,34,82

Eggshell thinning induced by dichlorodiphenyldichloroethylene (DDE) is species specific. Organochlorines reduce levels of androgens in males and estrogen and progesterone in females. Levels of thyroxine in both sexes decrease in a dose-related fashion. There are also links between hyperthyroidism, PCB's and dichlorodiphenyltrichloroethane (DDT).41 Chlorinated hydrocarbons induce changes in the metabolism of steroid hormones by mixed function oxidases (MFO).82

BIRD BEHAVIOR

A range of behavioral traits can be attributed to nutritionally imbalanced diets, inappropriate dietary ingredients, and dietary exposure to pesticides (Table 4.2.16). These include changes to vocalization patterns and breeding behavior. Behavioral traits of birds also need to be evaluated when converting birds to formulated diets (see Chapter 3, Concepts in Behavior, Section III Pubescent and Adult Psittacine Behavior). The subjects of high-fat and high-sugar diets along with elevated sodium are presented.

Dietary Influences on Vocalization Patterns

Changes in vocalization patterns have been reported in cockatiels maintained on diets with deficient or excessive levels of vitamin A. ⁵⁸ Excessively high levels of vitamin A (100,000 IU/kg) increase the number of vocalizations and reduce the peak frequency of vocalizations, while moderately excessive levels of vitamin A (10,000 IU/kg) result in a reduction in peak amplitude and total power. These changes may influence breeding behavior, social interactions and responses of adults to begging behavior of chicks.

Diet and Behavioral Changes

Reproductive behavior, normally regulated by photoperiod, can be influenced by dietary components.

Additional seeds stimulate breeding behavior in African grey parrots. Endocrine malfunction has been implicated in anecdotal studies of male budgerigars on all-seed diets that display continuous feeding behavior towards a mirror. Reducing the synthetic vitamin A content of food fed to lorikeets reduced defecation in nest boxes (Unpublished data, D. McDonald). See Chapter 3, Concepts in Behavior, Section III Pubescent and Adult Psittacine Behavior.

DIET CONVERSION CHALLENGES

Modifying a bird's diet is one of the biggest behavioral challenges. Most issues can be overcome with patience and perseverance. Educating the owner about the benefits of a formulated diet versus a seed-based diet is the first challenge. Feeding the new dietary items early in the morning when the birds are most hungry is beneficial, but dietary changes should be undertaken gradually. If birds continue to have problems with acceptance of new dietary items, placement near birds that are already feeding on similar foods is beneficial as birds usually mimic feeding habits of other birds. Mixing the new diet with a favorite fruit can be helpful; mushy fruit works best as it sticks to the formulated food. Remove the fruit after 4 to 6 hours to avoid consumption of spoiled food.

An important concern is the bird's refusal to eat or significant weight loss. Although weighing the bird in grams on a daily basis is the best method of monitoring adequate food consumption, monitoring droppings can also indicate if the bird is eating enough. Prior to the diet change, note the number and character of the droppings (color, amount, liquid, form, shape, lack of odor, staining). See examples in Chapter 6, Maximizing Information from the Physical Examination. Any change in volume and number of droppings, usually a dramatic decrease in amount, indicates insufficient consumption. Character of droppings will change as the bird consumes more formulated diet. Weight fluctuations greater than 10% are considered

problematic. Even if provided with surplus food, birds can starve to death if they don't consume the food offered. Therefore, it is imperative to immediately return a bird to its original diet if it refuses to eat the new diet. The following guidelines should be given to owners when a diet conversion is being initiated.

Tips for Converting Birds to a Formulated Diet

- Visit the avian veterinarian for a general health exam to decide if the bird is healthy enough to undergo a diet change at this time.
- Discuss which formulated product is best for the bird.
- Determine the goal body weight that is appropriate for the bird.
- Purchase a gram scale and learn how to use it correctly.
- Weigh the bird at the same time every morning for a week to establish normal fluctuations in weight.

 Report any serious fluctuations (10% or more) to the avian veterinarian.
- Mix half formulated diet and half the old diet. Expect the bird to exhibit negative behavior by throwing the pellets/nuggets at owner, screaming, yelling, and having tantrums. Talking to the bird may soothe it. As the bird starts to eat the formulated diet, gradually reduce the amount of the old diet and increase the proportion of the new diet.
- Remove all perches from cage so the bird is forced to sit on the food dish or put the bird in a plastic or glass box (aquarium) and sprinkle food on the floor. Provide a small water container—no toys.
- Place formulated food on a mirror located on the floor (Figs 4.2.33a,b).
- Place the bird in a cage with another bird that is already consuming a formulated diet. Do not provide any seed and separate birds at night. If the bird has not consumed any of the formulated food by evening, provide it with seed.
- Once it starts to eat, place a bowl of formulated food near the highest perch.
- Feed the old diet for 30 minutes in the morning, remove and replace with formulated food for remainder of the day. Feed the old diet for 30 minutes at night if formulated diet is not eaten.
- Grind formulated food in a blender (or purchase a mash product) and mix crushed millet in with the mash.
- Using a less palatable seed (hulled white millet), break the seeds up in a blender with the pellets. After a few days use less ground millet.
- Thoroughly mix bird's favorite fruit into formulated diet so bird gets a mouthful of new diet with fruit.
- Under the guidance of an avian veterinarian, try returning to hand feeding a juvenile formula with a

Fig 4.2.33a | Budgerigar that has become infatuated with its image in a mirror.

Fig 4.2.33b | Cockatiel in a container with only a mirror. Food is placed on the mirror. Return the bird to its own cage at night for regular diet and water. Replace in mirror box next day after having at least 30 minutes to eat regular diet and drink. Diminish the time with seeds daily until weaned.

syringe and then wean to formulated food.

• Very small particles of formulated foods seem more acceptable to small birds

If patience and persistence doesn't pay off, it is best to board the bird under clinical supervision. The veterinarian can convert the bird to the new diet while carefully monitoring weight and health of the bird. Most birds switch diets very quickly when removed from the "comfort" of the home environment. Avian veterinarians generally have more experience with dietary changes. Birds should be left for a sufficient period of time to ensure conversion is complete ie, held for 2 to 10 days. Wait until the bird maintains body weight for at least two days after normal diet has been totally removed. It is best that the bird is not returned to the same routine at home (ie, move cage, redecorate cage, don't place in kitchen at mealtime).

Some of the IDC clinical signs are idiosyncratic in nature. A 20-year old cockatiel maintained solely on sunflower seeds or a 50-year-old Amazon provided with chicken bones, seeds, nuts and table foods may never present with the advanced signs of a clinical nutritional disorder. However, this should be seen as the exception and not the rule. Additionally, individual birds may develop clinical signs of the IDC at different rates or to varying degrees.

While problems associated with the integument can precede breakdown of other systems, they are seldom recognized in the early stages of the IDC. Therefore, digestive upsets associated with gastroenteritis and ileus are more likely to instigate an investigation into yeast or coliform bacterial infection rather than dietary history. A proliferation of meetings, publications, investigative consultancies, analytical laboratories and therapies aimed at the presenting problems over the past 30 years have all contributed to a better understanding of illnesses in pet birds. While secondary problems associated with any one of dozens of common, yet serious, secondary pathogens still warrant attention, preventive medicine remains the most effective therapy.

Calcium Metabolism

MICHAEL STANFORD, BVSc, MRCVS

Calcium plays two important physiological roles in the avian subject. First, it provides the structural strength of the avian skeleton by the formation of calcium salts. Second, it plays vital roles in many of the biochemical reactions within the body via its concentration in the extracellular fluid.3 The control of calcium metabolism in birds has developed into a highly efficient homeostatic system, able to quickly respond to increased demands for calcium required for both their ability to produce megalecithal eggs and their rapid growth rate when young.^{2,3} Parathyroid hormone (PTH), metabolites of vitamin D₃ and calcitonin, regulate calcium as in mammals, acting on the main target organs of liver, kidney, gastrointestinal tract and bone. 2,3,11,24 Estrogen and prostaglandins also appear to have an important role in calcium regulation in the bird.2,3

There are distinct differences between the mammalian and avian systemic regulations of calcium. The most dramatic difference between the two phyletic groups is in the rate of skeletal metabolism at times of demand. The domestic chicken will respond to hypocalcemic challenges within minutes compared with response to similar challenges in mammals that can take over 24 hours.11 This is best demonstrated by an egg-laying bird where 10% of the total body calcium reserves can be required for egg production in a 24-hour period. 10 This calcium required for eggshell production is mainly obtained from increased intestinal absorption and a highly labile reservoir found in the medullary bone, normally visible radiographically in female birds. The homeostatic control of the medullary bone involves estrogen activity.2 Due to the rapid metabolic responses in the avian skeleton, it has become a common model for skeletal studies concerning the regulation of calcium.

Abnormalities of calcium metabolism are common in the poultry industry, leading to poor production and growth defects, in particular, tibial dyschondroplasia in broiler chickens kept indoors. Due to the economic status of the poultry industry, calcium metabolism has been well researched in production birds, including the assessment of the importance of dietary calcium, vitamin D_3 and their interaction with ultraviolet light, especially in the UV-B spectrum (315-280 nm). $^{1.4,14,24}$

In captive pet birds, disorders of calcium metabolism also are common, ranging from osteodystrophy in young birds (due in part to the greater calcium requirement in young growing birds) to hypocalcemic seizures and egg binding in adults. 5,6,7,16 Although African grey parrots (*Psittacus erithacus*) are considered to be especially susceptible to disorders of calcium metabolism, problems have been reported in a variety of captive species. The husbandry requirements with respect to calcium have been poorly researched in pet birds in the past, and much of our present knowledge is extrapolated from work with poultry.

Calcium Regulation in Birds

CALCIUM

Calcium exists as three fractions in the avian serum: 1) the ionized salt, 2) calcium bound to proteins, and 3) as complexed calcium bound to a variety of anions (citrate, bicarbonate and phosphate). Ionized calcium is the physiologically active fraction of serum calcium, with a role to play in bone homeostasis, muscle and nerve conduction, blood coagulation and control of hormone secretions such as vitamin D₃ and parathyroid hormone. The majority of the protein-bound calcium is bound to albumin and considered to be physiologically inactive. Any change in serum albumin levels will directly affect the total calcium level. The binding reaction is strongly pH-dependent, so an increase or decrease in pH will respectively increase or decrease the protein-bound calcium fraction. The significance of the small, complexed calcium fraction is unknown at the present time, but any disease state that affects the levels of the binding anions would be expected to significantly alter calcium levels.8,21,22

The ionized calcium level appears to be maintained within a tight range in the normal individual compared with the total calcium level, which fluctuates with serum protein concentrations, and any major change in the serum ionized calcium level is likely to be of pathologic significance. Ionized calcium concentrations are regulated by the interaction of PTH, vitamin D₃ metabolites and calcitonin in response to changing demands.

VITAMIN D,

The vitamin D₃ metabolism of birds has been extensively reviewed. 1,3,4,24,25 Following the identification of vitamin D₃ metabolic pathways, vitamin D₃ now is considered to be a steroid hormone exhibiting feedback relationships in response to calcium requirements.8 The main role of vitamin D₃ is in the control of bone metabolism by strictly regulating mineral absorption, but more recently it has been found to have profound effects on the immune system, skin and cancer cells.1 Due to the importance of the vitamin's role in bone development and the requirement for UV light in the metabolic conversion of provitamin D₃ to vitamin D₃, the commercial availability of dietary vitamin D₃ has been essential to allow the indoor production of poultry.4 Vitamin D occurs naturally in plants as ergocalciferol (vitamin D₂) and this will function in mammals as well as vitamin D₃, but birds do not respond well to dietary vitamin D2. This is due to increased renal clearance of vitamin D2 rather than lack of intestinal absorption.10

It has been established that the domestic chicken secretes 7-dehydrocholesterol (provitamin D_3) onto the featherless skin. It has recently been shown that there are ten times more provitamin D_3 on the featherless leg skin than on the back, indicating the importance of this area for vitamin D_3 metabolism.²⁵ Conversion of the provitamin D to cholecalciferol (vitamin D_3) occurs by a UV-B light-dependent isomerization reaction. Cholecalciferol is a sterol prohormone that is subsequently activated by a two-stage hydroxylation process.

Cholecalciferol is initially metabolized to 25-hydroxycholecalciferol in the liver; 25-hydroxycholecalciferol is transported to the kidney via carrier proteins and converted to either 1,25-dihydroxycholecalciferol or 24,25dihydroxycholecalciferol, the active metabolites of cholecalciferol in the domestic fowl. The most significant active metabolite of vitamin D₃ in domestic chickens is 1,25-dihydroxycholecalciferol, which displays a hypercalcemic action.^{9,21} While not significant in mammals, 24,25dihydroxycholecalciferol is thought to have a special active role in the laying hen.2 The synthesis of 1,25- dihydroxycholecalciferol is tightly regulated by PTH, depending on the calcium status of the bird. The metabolite regulates calcium absorption across the intestinal wall by inducing the formation of the carrier protein calbindin-D28k. The presence of this protein reflects the ability of the intestine to absorb calcium. Calbindin-D28k also is found in the wall of the oviduct, and levels rise during egg laying, although this process is not directly related to the actions of 1,25-dihydroxycholecalciferol. Bone formation is stimulated by 1,25- dihydroxycholecalciferol, which induces osteoclastin production from osteoblasts. In egg-laying birds, 30 to 40% of the calcium required

for eggshell formation is acquired from medullary bone. The control of this highly labile pool of calcium involves both 1,25- dihydroxycholecalciferol and estrogen activity. The function of vitamin D_3 is reliant on the presence of normal vitamin D_3 receptors. The receptors have been found in bone, skin, skeletal muscle, gonads, pancreas, thymus, lymphocytes and pituitary gland. 2,3,4,8,11,14,24,25

If vitamin D_3 is supplied in the diet, it can be absorbed with 60 to 70% efficiency. In most situations, there is a compromise between the amount of dietary vitamin D_3 administered (on the basis of economy and toxicity) and UV light provided for natural vitamin D_3 formation.¹⁰

PARATHYROID HORMONE (PTH)

The parathyroid glands produce PTH from the chief cells in response to a low ionized calcium level.8,10 As in mammals, PTH has an essentially hypercalcemic action in birds, and if a parathyroidectomy is performed in quail, the birds respond with severe hypocalcemia unless calcium is given in the diet.3 Birds appear more sensitive to PTH than mammals, reacting to intravenous injections of the hormone within minutes with a rise in blood calcium levels.^{2,3,11} The blood ionized calcium level feeds back on the chief cells in the parathyroid gland to tightly control secretion of the hormone. The hormone uses the kidney and the bone as its main target organs in birds.3 In the bone, the hormone has rapid effects measurable within 8 minutes of administration compared with hours in mammals, so PTH is probably at least partially responsible for the speed of calcium metabolism in the bird.2

PTH directly stimulates osteoclasts to resorb bone. The hormone also will actively stimulate osteoblast activity, and it is thought that PTH-stimulated osteoblasts regulate osteoclast activity, providing the precise control system necessary in avian skeletal turnover.^{2,3}

PTH binds to osteoclasts, increasing bone resorption by stimulating their metabolic activity and division. PTH also has direct influence on both calcium and phosphorus excretion in the bird. Calcium excretion is increased and phosphorus decreased following parathyroidectomy. These changes can be reversed by injections of PTH.

PTH has a different structure in birds than in mammals. It consists of an 88-amino acid chain, compared with 84 in mammals, and there is a lack of homology between the two molecules. The greatest similarity is found in the 1-34 segment of the chain, which also is responsible for much of the activity of the hormone.^{3,8} Unfortunately, this segment has a short half-life, and mammalian assays tend to assess the middle and carboxyl-terminal regions of the amino acid chain where homology with avian PTH

is poor.⁸ This may explain why PTH has appeared difficult to measure in the avian subject and is poorly researched at the present time, although circulating levels are believed to be low compared with mammals. An inverse relationship has been found between PTH concentrations and ionized calcium levels in the laying chicken, indicating that PTH has at least an important role in calcium regulation during this period. This response is very efficient during egg production, with PTH levels increasing due to the greater demand for calcium. A recent study in African grey parrots investigating hypocalcemia has used a mammalian 1-34 PTH enzymelinked immunosorbent assay with consistent results.¹⁸

PARATHYROID HORMONE-RELATED PEPTIDE (PTHRP)

PTHrP is a second member of the PTH family, originally discovered as a cause of hypercalcemia in malignancy in man and now the subject of much clinical research. PTHrP has three isoforms of 139, 141 and 173 amino acids, all with identical sequences through to amino acid 139. The hormone has distinct structural homology with PTH, suggesting a common ancestral gene. There is distinct homology between the structure of mammalian and avian PTHrP in the 1-34 segment, as has been found with PTH. PTH and PTHrP share a common receptor. Many tissues in the chicken embryo contain levels of PTHrP. In chickens as in man, PTHrP is thought to play many regulatory and developmental roles in a variety of tissues. Concentrations of PTHrP have been shown to rise in the shell gland of the chicken during the calcification cycle, affecting smooth muscle activity in the gland. Levels of PTHrP return to normal once the egg has been laid. PTHrP has been shown to have effects on bone resorption in the chicken embryo.3

ULTIMOBRANCHIAL GLANDS

The ultimobranchial gland in birds produces calcitonin. It is a 32-amino acid hormone that exerts an essentially hypocalcemic effect in response to rising serum ionized calcium levels.3 The levels of circulating calcitonin in birds, amphibians and possibly sub-mammals are high and readily detectable compared with PTH. The bioactivity of calcitonin also varies among phyletic groups, with fish calcitonin exhibiting the most potent effect. In the bird, calcitonin levels increase following injections of calcium. There is a direct correlation between calcitonin levels and dietary calcium concentrations (and, hence, serum calcium levels). Although calcitonin has been shown in man to exert its hypocalcemic effects mainly by inhibiting osteoclastic bone resorption, its biological action in the bird remains surprisingly unclear despite the high circulating levels of the hormone in this group.

PROSTAGLANDIN

Prostaglandins are powerful facilators of bone resorption, with hypercalcemic effects similar to PTH and vitamin D₃ metabolites. The osteoclast appears to be the site of action for prostaglandin. Injections of prostaglandin into chickens will produce hypercalcemia, and the use of prostaglandin antagonists will produce hypocalcemia.3

ESTROGEN

Estrogens promote the formation of the vitellogenins from the liver. These are lipoproteins that are incorporated into the egg yolk. They bind calcium, and their production is followed by a rise in serum calcium levels. This estrogen-controlled hypercalcemic effect is not seen in mammals and is thought to be due to the need to produce large calcified eggs, requiring a rapidly mobilized source of calcium. Estrogens also influence the mobilization of medullary bone during the egg-laying cycle (and also during the nocturnal fast). The effect of estrogen on avian medullary bone is a large research area due to the importance of estrogen in maintaining bone mass in postmenopausal women.^{2,3}

Investigating Abnormalities of Calcium Metabolism

CALCIUM

The measurement of serum ionized calcium provides a more precise estimate of an individual's calcium status than does total serum calcium, especially in the diseased patient. 8,26 Unfortunately, the majority of veterinary pathology laboratories at the present time report only a total calcium value measured by spectrophotometer, reflecting the total combined levels of ionized calcium, protein-bound calcium and complexed calcium. This can lead to misinterpretation of calcium results in birds, as any change in protein-bound calcium levels is not thought to have any pathophysiological significance. 22,26 Measurement of total calcium in an avian patient with abnormal protein levels or acid-base abnormalities would not truly reflect the calcium status of the animal. Any state affecting serum albumin values in the blood will affect the total calcium concentration, leading to an imprecise result. In laying female birds, the serum albumin levels may rise by up to 100%. This would produce an inflated total calcium concentration due to an increased protein-bound calcium fraction, while not affecting the ionized calcium level. The binding reaction between the calcium ion and albumin is strongly pHdependent, so acid-base imbalances will affect ionized

calcium levels. Therefore, a patient with metabolic acidosis would be expected to show an ionized hypercalcemia level due to decreased protein binding. With an alkalotic patient, an ionized hypocalcemia would occur as the protein-binding reaction increases. Ionized calcium levels are therefore considered a far more accurate reflection of the patient's calcium status, especially in a diseased animal. In mammals, positive correlations have been found between albumin and total calcium levels.8,26 This enables formulae to be developed that "correct" total calcium levels for fluctuations in albumin levels. Recent research has suggested these corrected estimates of free calcium are inaccurate in 20 to 30% of cases in mammals.8 In mammals, the relationship between total calcium and albumin diminishes with the severity of the disease, and the correction formulae are now thought to be less useful. Previous research in psittacine birds found a positive correlation between albumin and total protein in African grey parrots, but not Amazons (Amazona spp.);12,13 more recent research in healthy African grey parrots has not indicated a significant relationship.21,22 In the majority of cases, the measurement of ionized calcium is preferred in both mammals and birds.

Ionized calcium levels are measured by ion-specific electrodes. Analyzers using ion-selective electrodes are increasingly available for use in veterinary clinics. The methodology employed by the analyzers is based on the ion-selective electrode (ISE) measurement principle to precisely determine the ion values. The analyzers are normally fitted with ISE electrodes to assay the electrolytes sodium, potassium and ionized calcium. Each electrode has an ion-selective membrane that undergoes a specific reaction with the corresponding ions contained within a particular sample. The membrane is an ion exchanger reacting to the electrical charge of the ion, causing change in the membrane potential or measuring voltage, which is built up in the film between the sample and the membrane. A galvanic measuring chain within the electrode determines the difference between the two potential values on either side of the membrane of the active electrode. The potential is conducted to an amplifier by a highly conductive inner electrode. The ion concentration in the sample is then determined by using a calibration curve produced by measuring the potentials of standard solutions with a precisely known ion concentration. Blood samples for ionized calcium assays should be drawn into heparin and analyzed as soon as possible after venipuncture, as changes in the blood pH of the sample will affect the accuracy of the ionized calcium levels (ie, contact with carbon dioxide in the air will reduce the pH of the sample). Despite this, a study in dogs suggests that samples will not be adversely affected if not assayed for up to 72 hours, so it is possible to use external laboratories.¹⁷ This has been the

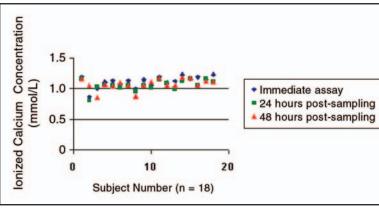

Fig 5.1 | Effect of sample handling delay on ionized calcium concentrations. There was no significant difference between ionized calcium concentrations in the same sample despite delays of up to 48 hours. The samples were stored at 3-5° C prior to analysis.²²

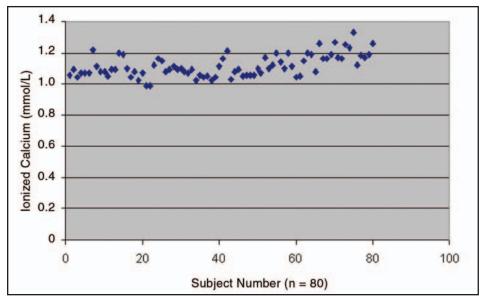

Fig 5.2 | Serum ionized calcium concentrations in 80 healthy captive African grey parrots. The ionized calcium concentrations are all within a tight range. The normal range was found to be 0.96-1.22 mmol/L.

author's experience with avian samples, but it is advisable to fill the sample tubes to minimize contact with the air²² (Fig 5.1). It also is important to chill the samples immediately to reduce glycolysis by the red blood cells, which continue to produce lactic acid as a byproduct, reducing the pH of the sample.

A recent study in healthy African grey parrots indicated a narrow normal range for ionized calcium levels, but a wide variation in total calcium levels due to protein fluctuated among birds^{21,22} (Figs 5.2, 5.3). The study did not reveal any significant correlation between albumin levels and total calcium levels in healthy birds. It was shown that using total calcium values in isolation would lead to misdiagnosis of disorders of calcium metabolism in this species. Of 394 samples submitted from African grey parrots into the practice laboratory in 2001, 54 samples (13.17%) had a low ionized calcium level despite having

normal total calcium concentrations, suggesting that hypocalcemia is potentially under-diagnosed in this species.²² In mature female birds, hypercalcemia might be over-diagnosed due to increased protein-bound calcium producing a high total calcium level, but ionized levels would not be affected. Due to the potentially large fluctuations in albumin levels in adult birds compared with mammals, it is considered essential wherever possible to measure ionized calcium levels.

VITAMIN D,

The measurement of 25-hydroxycholecalciferol is considered the best assessment of vitamin D_3 status in the avian subject due to a longer half-life than other vitamin D_3 metabolites.⁸ There are assays available for the other metabolites of vitamin D_3 and it is important to ensure that any assay has been optimized for the metabolite of interest. Until recently, radioimmunoassays were the

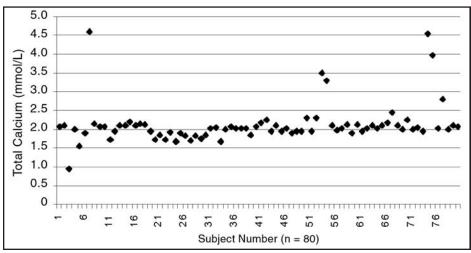

Fig 5.3 | Serum total calcium levels in the same 80 healthy captive African grey parrots as Fig 5.2. The total calcium concentrations were outside the normal range (2.0-3.0 mmol/L) in several birds despite normal ionized calcium levels. This fluctuation in the total calcium concentration was due to protein variations in individual birds and has no pathological significance. This demonstrates the importance of measuring ionized calcium wherever feasible rather than total calcium.

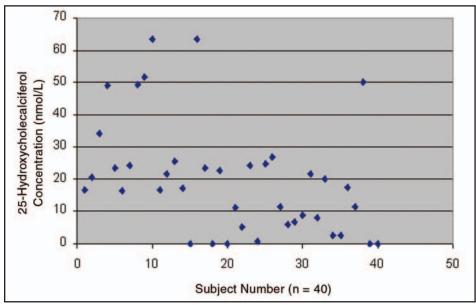

Fig 5.4 | 25-hydroxycholecalciferol concentrations in seed-fed African grey parrots. There was a wide variation in vitamin D levels. It is postulated that this is due to both fluctuations in UV-B levels received by individual birds and low dietary vitamin D.

only commercial assays available for both 25-hydroxy-cholecalciferol and 1,25-hydroxycholecalciferol. An ELISA test for 25-hydroxycholecalciferol has recently been developed with the advantages of both convenience and economy. This assay has been shown to correlate well with the radioimmunoassays.⁸ This has allowed research to be carried out in the *Psittacus* species. A recent study in African grey parrots (a genus known to suffer from hypocalcemia) indicated a wide variation in 25-hydroxy-cholecalciferol levels in seed-fed birds^{19,20} (Fig 5.4). Any 25-hydroxycholecalciferol results should be interpreted within the context of the diet and the levels of UV light received by the bird.²⁰ Recent research in

psittacine birds has suggested that serum vitamin D_3 levels can be affected by both varying levels of dietary vitamin D_3 and UV-B light exposure.²³ Blood should be drawn into heparin and preferably frozen immediately after venipuncture until the assay can be performed. The use of vitamin D_3 assays will have an increasing use in avian medicine due to the common presentation of calcium disorders, both in terms of clinical disease and poor reproductive results. Vitamin D_3 assays could possibly be useful for reptiles — another group that suffers problems with calcium metabolism, in many cases due to poor husbandry.¹⁵

Fig 5.5 | A 5-week-old African grey parrot with severe nutritional osteodystrophy. There was radiographic evidence of pathological fractures in both tibiotarsi and humeri with severe spinal malformation. The bird was euthanized. Histopathology of the parathyroid glands confirmed vacuolated hypertrophic chief cells suggestive of nutritional secondary hyperparathyroidism. The bird had been parent-reared by adults fed an unsupplemented seed mix.

Fig 5.6 | Lateral radiograph of a 12-week-old African grey parrot with severe osteodystrophy. There is severe deviation of both tibiotarsi with marked deviation of the spine. The chick had been parent-reared by adults fed an unsupplemented seedbased diet. The bird was humanely euthanized.

ASSAY FOR PTH

PTH is very labile and any assay requires exacting sample handling to produce good results. Blood should be drawn into EDTA and either assayed immediately or frozen to -70° C within 1 hour of venipuncture. The majority of human measurements involve a two-site radioimmunoassay in an attempt to reduce the interfering effect of the many cleavage products of PTH that have long half-lives. Most human assays concentrate on the middle and terminal segments of the PTH molecule due to the very short half-life of the biologically active 1-34 section. A human research kit for 1-34N section PTH has been used to assay PTH in African grey parrots with consistent results. This study indicated that as ionized calcium levels rose in a group of 40 African grey parrots, PTH levels fell. Unfortunately, the assay for PTH 1-34N is too intricate for routine use at the present time and, in the author's opinion, intact 1-84 PTH assays are not useful in psittacine birds.8,13,18

Effects of Husbandry on Calcium Metabolism in Psittacine Birds

The effects of altering dietary vitamin D_3 , calcium or exposure to different levels of UV light have been well researched in poultry.^{3,4,10,14,24} Deficiencies in any of these parameters will lead to poor production and skeletal disorders such as tibial dyschondroplasia.³ Extensive research has produced published results, enabling the poultry industry to select varying levels of dietary vitamin D_3 and calcium in accordance with the amounts of UV

supplied. If domestic poultry are receiving no UV light, then all the cholecalciferol must come from the diet. ¹⁰ The domestic fowl does not have a dietary requirement for vitamin D₃ if it receives adequate UV-B radiation. ¹⁰

Unfortunately, caged birds have not been extensively researched, but most would be expected to receive a poor diet with inadequate UV light. Seed-based mixes traditionally used for feeding captive parrots have low levels of both vitamin D₃ and calcium.^{5,16,20,21} In addition, they can contain high levels of phosphorus that can bind the calcium in phytate complexes. 10 Chronic deficiency of vitamin D would be expected to lead to hypocalcemia and secondary hyperparathyroidism. Vitamin D is obtained by birds directly from the diet and by the action of UV-B on vitamin D precursors in the cutaneous tissues. Either a deficiency in dietary vitamin D or lack of available UV-B light would be expected to produce a vitamin D-deficient bird, potentially leading to subsequent problems with calcium metabolism.3,10 Hypocalcemia is a common syndrome in avian subjects, with African grey parrots (Psittacus erithacus) in captivity appearing particularly susceptible, although the etiology is still unconfirmed. 5,6,7,16 Affected birds present clinically with a variety of neurological signs, ranging from slight ataxia to seizures, which respond to calcium therapy.21,22 In adult females, egg binding or poor reproductive performance is a common presentation. In young African grey parrots, osteodystrophy also is a common presenting clinical sign⁵ (Figs 5.5-5.8). The growing birds can be affected by bony deformities that range from subtle radiographic changes to obvious gross deformities in both the long bones and spinal column. Radiography has been routinely used to demonstrate juvenile osteodystrophy in many other species of birds. In a recent study,

Fig 5.7 | An adult African grey with osteodystrophy. The bird has characteristic bending in the tibiotarsi. The condition was successfully corrected by osteotomy and fixation of both leas.

Fig 5.8 | Ventral dorsal radiograph of the bird in Fig 5.7. There is severe deviation in both tibiotarsi with folding pathological fractures. There also is evidence of abnormal skeletal development in both wings.

16 of 34 feather-plucking birds examined radiographically as part of a normal work-up revealed evidence of osteodystrophy.5 The condition will be permanent and deteriorates as the birds increase in weight, which puts increased pressure on the deformed bones and frequently requires corrective surgery.

A recent study in African grey parrots has shown that it is possible to produce changes in calcium parameters by varying husbandry conditions as in poultry. 21,23,25 The study has demonstrated the effects of feeding a formulated nugget dieta with increased levels of vitamin D3 and calcium compared with a seed-fed control group. The nugget diet produced a statistically significant increase in both the ionized calcium levels and 25-hydroxycholecalciferol levels over the seed-fed group^{21,25} (Figs 5.9, 5.10). This was reflected in improved breeding performance in the nugget-fed group. These young birds developed without radiographic evidence of osteodystrophy.

In the same study, both the seed- and nugget-fed groups revealed a significant increase in 25-hydroxycholecalciferol and ionized calcium concentrations when they were exposed to artificial UV-B radiation²³ (Figs 5.11, 5.12). The nugget-fed group under the same UV levels revealed significantly higher concentrations of vitamin D₃ and ionized calcium over the seed control group.23 The initial observations from this study suggest that UV light levels also are important factors in the vitamin D metabolism of captive birds in addition to diet. In the future, it will be possible to supply diets with varying amounts of vitamin D depending on the ambient supply of UV-B light

available to captive birds. Initial work by the author with South American species has shown that they do not appear to be as dependent as African grey parrots on UV-B light for maintaining adequate vitamin D levels (M. Stanford, unpublished data). This might explain the prevalence of disorders of calcium metabolism in African grey parrots compared with other psittacine birds. South American rain forest has a dense canopy compared with African forests, reducing the UV-B light levels reaching the birds, so their vitamin D metabolism would be expected to be different from those of African birds.

These studies show that it is important that breeders feed their birds a diet that contains adequate calcium and vitamin D. It also is important to supply adequate UV-B radiation to captive birds kept indoors. This would be expected to help prevent the many expressions of hypocalcemia seen specifically in African grey parrots and other susceptible species. This includes the parent birds, because the female birds lay down medullary bone starting about 6 weeks prior to laying eggs. The nutrition of female birds appears to affect the early development of the chicks. In a recent study in African grey parrots, parent-reared juveniles showed radiographic evidence of osteodystrophy at 8 weeks if the parents were fed seed-based diets. The young from nugget-fed parents had no radiographic signs of osteodystrophy at 12 weeks 21,25 (Figs 5.13, 5.14). See Chapter 4, Nutritional Considerations, Section I Nutrition and Dietary Supplementation.

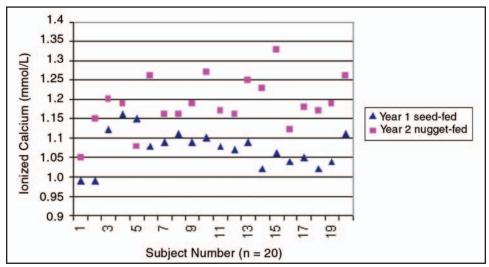

Fig 5.9 | Effect of diet on ionized calcium concentrations in African grey parrots. There was a significant increase in the serum ionized calcium concentrations in birds fed a formulated nugget diet^a compared with the same birds fed a seed-based diet.

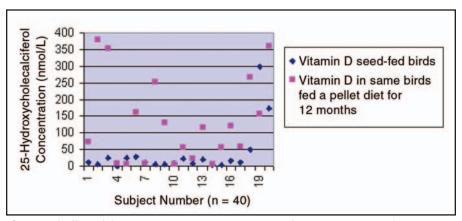

Fig 5.10 | Effect of diet on vitamin D concentrations in African grey parrots. There was a significant increase in the 25-hydroxycholecalciferol concentrations in birds fed a nugget diet^a compared with the same birds fed a seed-based diet.

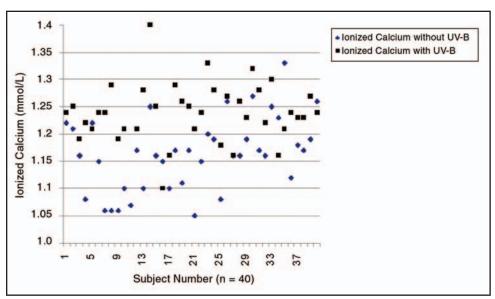

Fig 5.11 | Effect of UV-B supplementation on ionized calcium concentrations independent of diet fed. There was a significant increase in ionized calcium concentrations in both the seed- and nugget-fed groups exposed to 12 hours of UV-B light in every 24 hours.

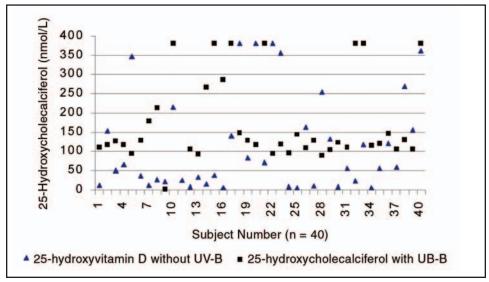

Fig 5.12 | Effect of UV-B supplementation on 25-hydroxycholecalciferol concentrations in African grey parrots independent of diet fed. There was a significant increase in 25-hydroxycholecalciferol concentrations in both seed- and nugget-feda groups exposed to 12 hours of UV-B light in every 24 hours.

Maximizing Information from the

Physical Examination

BOB DONELEY, BVSc, FACVSc (Avian Health); GREG J. HARRISON, DVM, Dipl ABVP-Avian, Dipl ECAMS; TERESA L. LIGHTFOOT, DVM, Dipl ABVP-Avian

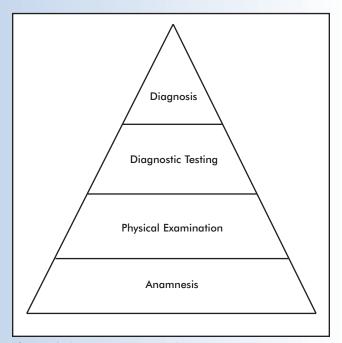

Fig 6.1 | The Diagnostic Pyramid

The last ten years have seen amazing advances in diagnostic testing capabilities in avian medicine. Tests that were not even considered a decade or two ago are now commonplace. However, the cornerstone of good avian medicine is still the careful evaluation of the patient. Diagnostic tests are an important part of that evaluation, but they are not the whole evaluation. Their use is only a part of a continuum that starts with a careful anamnesis and concludes with a diagnosis. This can be illustrated by the diagnostic pyramid shown (Fig 6.1).

Astute clinicians will move carefully through these levels, refining their differential list through careful history taking, physical examination and selection of diagnostic testing until a final diagnosis (or at least a much shortened list of differentials) is reached.

Understanding the Masking Phenomenon

A common misconception held by many bird owners and veterinarians is that birds are not very resistant to illness. To the novice it often appears that birds show signs of illness one day, are at the bottom of their cage the next, and dead the day after. This misconception has stemmed from two sources.

First, many of the birds seen in practice are only a few generations descended from wild birds. As such, they retain many of the protective instincts inherited from their forebears. Many avian species kept as companions are relatively low on the food chain. These protective instincts have been developed to avoid drawing the

Fig 6.2a | The bird's natural masking phenomenon misleads owners and many veterinarians. They think the bird is fine, until the bird decompensates and shows overt signs of illness. This blue budgerigar is showing the signs of the latter stages of illness and is "sleeping" and "fluffed up." In the same environment, the yellow bird is keenly alert.

Fig 6.2b | Observing a caged bird is an art well worth perfecting. Outwardly, this dead canary appeared fine to the owner who brought the bird to the veterinarian. The bird died moments after examination.

Fig 6.2c | This canary's illness has wasted away all the pectoral muscle. One must observe the bird in a quiet situation — waiting a few minutes for the masking behavioral defense to wane and the fluffing to recur. A history of a small bird that has not eaten in a day and has scant feces denotes a very sick bird. See discussion under Fig. 6.42a-d prior to handling such a sick bird.

attention of predators. One such instinct is often known as the "masking phenomenon." Predators are naturally drawn to prey that look or behave differently from others. Unusual coloring, weakness or lameness can single out a bird and make it attractive to a predator. A natural instinct is therefore to avoid appearing "different." A sick bird will make a determined effort to look healthy, even in the absence of predators. The classical "sick bird look" we usually associate with illness — fluffed feathers, closed eyes, lethargy - only develops when the bird is incapable of masking these signs (Fig 6.2a). Therefore, many of the patients presented to veterinarians are past the initial stages of their illness and are now decompensating rapidly.

Secondly, due to lack of experience, most owners and many veterinarians may miss subtle changes in a bird's behavior or appearance that are indications of a health problem. Overlooking these early signs, combined with the bird's efforts to mask obvious clinical signs, invariably leads to the delayed detection of illness and the presentation of the bird in extremis (Figs 6.2b,c). It is important that veterinarians learn to recognize early signs of illness, and educate their clients, so that illnesses can be detected before becoming too advanced. A physical examination form, used routinely by veterinarians and support staff, allows thorough and methodical documentation of the essential parameters of the physical examination (Fig 6.2c). The "masking phenomenon"

and the ease with which early clinical signs can be overlooked highlight the importance of regular health examinations for the companion bird. Long-standing conditions such as malnutrition can be detected and corrected before the bird begins to decompensate and shows overt signs of illness.

History Taking

The collection of an accurate and thorough history of a patient is as crucial to making a diagnosis as is the physical examination and comprehensive diagnostic testing. A good history can alert the clinician to likely problems and allow him/her to refine the diagnostic approach.

SIGNALMENT

The first step in obtaining a history is to gain as much information about the bird itself as possible. A good receptionist or technician can often obtain such information. The clinician should be familiar with avian taxonomy, sexual dimorphism, and species-specific behaviors. Clients are often unaware of some basic facts about their bird (such as species, sex and age). Veterinarians intending to see avian patients regularly need to acquire a working knowledge of commonly kept bird species and their physical characteristics. Such knowledge, while available in some publications, is generally acquired

through experience and through being proactive and inquisitive. This may require visiting other veterinarians, aviaries, avian pet stores and zoologic collections and will take some time to acquire.

The species of the bird is the first key piece of information. Many clients are unaware of the correct identification of their bird, or may refer to it by a local name unfamiliar to others. The cockatiel (Nymphicus bollandicus) is known all over the world as the cockatiel or 'tiel, except in Australia (the bird's native land), where it is more commonly known as the Quarrion or, in Western Australia, as the Weero (Figs 6.3a-f). The clinician needs to be able to recognize common species and have access to illustrated literature that will enable the clinician to confirm the scientific name and to identify unfamiliar species (see Chapter 2, The Companion Bird for selected photos). Knowledge of the species can offer the clinician vital clues to likely differential diagnoses for the sick bird and appropriate preventive medicine and husbandry during wellness examinations. For example, black cockatoos (Calyptorbynchus spp.) and some macaws require more fat in their diet than many other psittacines. The same diet fed to galahs (Eolophus roseicapillus) and budgerigars (Melopsittacus undulatus) can result in obesity, atherosclerosis or hepatic lipidosis. Species-specific behaviors, such as the alarm "snuffing" typical of Pionus spp., is often mistaken by new owners and veterinarians unfamiliar with this behavior as a pathologic respiratory condition.

The age of the bird, while usually difficult to determine once adult plumage has been attained, is another important part of the anamnesis. Juveniles are more susceptible to conditions such as rickets, polyomavirus, circovirus and bacterial infections, while adult birds are more likely to suffer from neoplasia, chronic malnutrition and degenerative conditions. While owners may not be sure of the exact age of their pet, they usually know how long they have owned it, and that may be sufficient for establishing an age-specific list of differential diagnoses.

Many psittacines are sexually monomorphic—or at least appear that way to their owners. Knowing the sex of a bird can be vital. For example, abdominal hernias are almost non-existent in male birds, while being relatively common in females; yolk-related peritonitis and cystic ovarian disease are obviously seen only in hens; cocks do not become egg bound. Do not accept the owner's assertion of their bird's sex unless they have proof of sex identification (ie, a history of egg laying or a certificate of sex identification that can be correlated with this bird). If such proof is not available, or the sex cannot be positively diagnosed by physical characteristics, surgical or DNA sexing may be required (Figs 6.4a,b).

PATIENT HISTORY

How long have the clients owned this bird? (Fig 6.5)

Birds that have been in the owner's possession for many years, with no recent exposure to other birds, are less likely to have infectious diseases (Fig 6.6) and are more likely to be suffering from underlying chronic conditions such as malnutrition or inadequate exercise. Recently obtained birds are more likely to have been in close contact with other birds and, as such, have possibly been exposed to infectious diseases (Figs 6.7-6.9).

Where did the owner obtain the bird?

With experience, the clinician will be able to identify "problem sources" of birds in the local area (ie, a certain breeder with a history of circovirus, bird fairs or a pet shop renowned for chlamydial problems). Developing a working knowledge of the quality of the sources of pet birds in your area can be a key element of patient evaluation in your practice (Fig 6.10) (see Chapter 2, The Companion Bird).

Is the bird aviary bred or wild-caught? (Fig. 6.11)

Wild-caught psittacines, although less common in recent times, are still coming into the pet market in certain parts of the world, such as in Europe. In countries such as Australia, Africa and South America, it is reasonably easy to obtain a bird from the wild. The challenge of taming a wild-caught bird can be daunting. Paradoxically, wild-caught (and therefore parent-raised) parrots that survive the rigors of capture and have adapted to interaction with humans, are much less likely to demonstrate the common behavioral problems of our domestically raised parrots. Feather plucking, vent prolapse, inappropriate screaming, and learned biting are all more prevalent in captive-raised African greys, Cacatua spp., and macaws (Ara spp.) Fortunately, improved techniques for raising these birds are being implemented, and both veterinary and client awareness of the need for continued attention to the emotional well-being of our parrots is increasing. As veterinarians, our responsibility is to inform the owners of the need for attention to and modulation of behaviors in their newly-acquired psittacine pet prior to the onset of problems. Suggesting and providing a contact for a knowledgeable parrot behavioral consultant can make the difference between a decadeslong rewarding human-pet bond and years of frustrated and dissatisfied co-existence (see Chapter 2, The Companion Bird and Chapter 3, Concepts in Behavior).

Parasitic infections (both gastrointestinal and hematogenous parasites) are more common in wild-caught birds. However, areas with outdoor aviaries in the USA often have significant and occasionally fatal super infections from various nematode species.

Fig 6.3a | Knowing the species, the sex and the name of the color mutation, such as in this cockatiel, makes an owner more comfortable with the avian veterinarian's knowledge. While most immature cockatiels resemble each other, mature cockatiels are usually sexually dimorphic. A mature gray male is shown here.

Fig 6.3b | These birds, if mature (over 9-12 months of age) represent the typical coloration of females of this species and color type. Females are lacking the bright yellow head in the normal gray colored cockatiel. Today's birds are seldom pure, but rather hybrid mutations. Coloration is not as dependable a factor in determination of gender in these mutation cockatiels. The bird on the left has some yellow on the head and would be said to be a hybrid — demonstrating normal grey female markings like the bird on the right but with the additional yellow of a pied. Females of the normal color have horizontal striping on the tail. When compared to the male in Fig 6.3a the body color is not the usual gray. This is a sign of a split. The coloration illustrated is likely to be "split" to cinnamon as well as lutino in order to demonstrate these colors.

Fig 6.3c | This yellow-headed cockatiel was thought to be a male until "he" laid an egg.

Fig 6.3d | Young pearl-colored cockatiels (pearlies) have this color pattern. The males revert to being very similar to Fig 6.3a, (normal grey), while the females retain the pearl pattern at maturity.

Fig 6.3e | Yellow (in this case) or white wing bars are present on the ventral surface in both cockatiel sexes until maturity. In immature females, these bars are present from the axillary region to the distal wing; in immature males they are present from the elbow joint to the distal wing. The bars are lost in mature males during their first adult molt.

Fig 6.3f | Pied-colored cockatiels are not as distinctly sexually dimorphic as normal grey cockatiels. Behavior may aid in gender determination in these mutations. Male cockatiels carry a melody while females usually produce only one or two notes.

Fig 6.4a | Mature budgerigars are sexually dimorphic in the nominate green birds and most color mutations. The male shown here has the characteristic male blue cere.

Fig 6.4b | A mature female budgerigar with normal brown hypertrophy of the cere. Note the lack of hyperkeratosis, despite her being an egg producing hen for several years.

Fig 6.5 | Some bird species, when properly cared for by the avian veterinarian and the owner, can be safely co-mingled, especially in spacious outdoor housing.

Fig 6.6 | Boarding facility at an avian veterinary hospital. Proper testing prior to boarding is critical. Testing for infectious diseases helps prevent disease outbreaks. A complete history and physical examination at the time of admission allows underlying disease, such as chronic malnutrition, to be detected, brought to the owner's attention and addressed. This protocol minimizes the chance that a bird will expire during boarding, and the subsequent assumption by the owner that the boarding was causative. Trained staff and attention to proper husbandry and monitoring of the birds are essential.

Fig 6.7 | A free-flying Amazon in an English aviculture facility is exposed to untested budgerigars and cockatiels. In this environment, this Amazon may serve as a carrier, intermediate host or mechanical vector between the untested budgerigars and cockatiels and the balance of the aviary. As such, it poses as much or more danger to other aviary birds as exposure to wild birds or infestation with rats or roaches.

Fig 6.8 | Wild birds at feeders outside bird facilities can be a source of infection. Wild lories at Currumbin Bird Park in Australia (see Chapter 21, Preventive Medicine and Screening).

Fig 6.9 | A cap, mask, coveralls or gown, boots, disposable containers and air filtration with HEPA-filters are used at a USDA pet bird quarantine facility. This demonstrates measures that must be taken to impose a true quarantine and limit disease transmission.

Fig 6.10 | These pet store birds have been properly tested and are kept housed as a single species. Individuals for display, sale and breeding are maintained in the store. When a collection is kept closed and is disease-free for several years, the incidence of disease will be much lower than in birds from pet stores with mixed, untested, open collections.

Fig 6.11 | Dr. Jan Hooimeijer examines a confiscated Jamaican parrot that was headed for the black market. Such birds are a constant source of diseases in the pet bird market and of diseases potentially devastating to the poultry industry.

Fig 6.12 | Perches over a fish pond and rock substrate over drains facilitate cleaning. The natural perches, artificial plants, and reed walls are difficult to sterilize. However, in a properly managed, disease-free collection, disinfection is not required.

Old World species of psittacines are also particularly susceptible to infection and death from sarcocystosis.

In Australia, the probability of a wild-caught cockatoo being affected with psittacine beak and feather disease (PBFD) is much higher than that of an aviary-bred bird. The same is true of African greys imported into the European Union (EU) from the wild. In the USA and the EU, captive African greys, eclectus, lories, sun conures and assorted other species can be infected with proventricular dilatation disease (PDD) (see Chapter 32, Implications of Viruses in Clinical Disorders). Macrorhabdosis is common in captive-raised budgerigars and lovebirds (see Chapter 30, Implications of *Macrorbabdus* in Clinical Disorders).

Is the bird hand-reared or parent-reared? If handreared, at what age was it pulled from the nest, or was the egg incubator hatched?

The health of juvenile birds is dependent largely on the health and nutrition of the parents (Fig 6.12). Handreared birds are dependent upon the quality of the hand-rearing formula being fed and the skill of the person performing the hand-feeding. Parent-reared birds tend to be more difficult to tame, unless they are handled on a regular basis before fledging. Hand-reared birds on the other hand, while usually more closely bonded to people, often have behavioral disorders associated with poor socialization, especially if reared in isolation. If a large number of chicks from different sources are reared in one facility, there is a higher probability of the spread of diseases such as polyomavirus and chlamydiasis. All of these factors need to be assessed during the history collection, especially when examining juvenile

birds. Birds sold prior to weaning, often to inexperienced owners, are predisposed to develop aspiration pneumonia. Behavioral problems are also common in babies hand-fed with the traditional methods (see Chapter 3, Concepts in Behavior).

Although incubator hatched eggs, when harvested by knowledgeable aviculturists, have a far less chance of accidental breakage or parental destruction, several negative consequences arise. Inappropriate incubator temperature or humidity can cause congenital deformities. The lack of antibodies from initial crop feedings by the parents may create an increased susceptibility to many diseases, some of which can prove fatal. Additionally, the consequence of deprivation from parental contact during the first days and weeks of life is not documented in birds, but extrapolation from other species would make it likely that a serious negative impact may arise from this isolation.

Does the client have other birds? Are they in contact with each other? Are any of these birds affected with similar clinical signs?

Other birds in the household may have many effects on the environment of the presenting patient. These could be a source of infection or susceptible to infection from a bird presenting to the practitioner with a contagious disease. It would be significant if a blue and gold macaw (Ara ararauna) presenting for dyspnea was being kept in the same room with a powderdown-producing species, such as an umbrella cockatoo (Cacatua alba). With feather destructive or self-mutilation behaviors, the presence or absence of other birds may affect (positively

Fig 6.13a | Birds are exposed to natural sunlight yet protected from over-exposure in this aviculturist's facility.

Fig 6.13b | Fluorescent lights may have cyclic flickering that is potentially harmful, both physiologically and psychologically.

or negatively) the emotional state of the affected bird.

Previous Medical History

The avian patient's previous medical history should be determined to the extent possible.

- Has the bird been ill before?
- If so, what were the clinical signs, tests performed, results of those tests, diagnosis and therapy administered?
- What was the bird's response to this therapy?
- Has the bird recently been treated with remedies purchased at a pet shop or supplied by a breeder?
 If so, what medication and for what period of time was or is it being administered?
- If the bird is presented for a second opinion or as a referral, may we request copies of the previous medical record?

HUSBANDRY

Is the patient an aviary bird, a companion bird, or a zoological specimen?

The husbandry of aviary birds and zoological specimens are discussed elsewhere in this book, and the reader is referred to the appropriate chapters. Assessment of a companion bird's husbandry must include the cage, the environment around the cage, and the bird's interaction with its environment.

Is the cage in which the bird was transported the bird's permanent cage?

If it is not, ask the owner to describe the permanent cage, using the guidelines contained in the following paragraphs.

Where is the cage located in the house?

In the kitchen, living room, individual's bedroom, or screened porch?

Is the bird able to remove itself from view?

Is it supplied with a hide box or comparable visual screen? Is it kept isolated, away from family activities, or in the middle of constant activity?

Is the bird permitted to get adequate sleep at night?

A common owner misconception is that covering a bird's cage, while that cage is located in a room with the lights and television on, is providing the bird with an environment conducive to sleep. Whether covered or not, the number of hours that a bird is supplied with sufficient darkness and quiet is critical to health — both emotional and physical.

Does the bird have access to direct, unfiltered sunlight on a regular basis? (Figs 6.13a,b)

Increased calcium absorption and metabolism from ultraviolet (UV) light exposure is beneficial to birds as it is for many other species. Recent research shows that some species may have an absolute requirement for UV light (see Chapter 5, Calcium Metabolism). In the appropriate climates or seasons, regular outdoor exposure to sunlight can have many additional benefits, both physical and psychological. Increased humidity, the sounds and sights of nature, breezes and changes in barometric pressure all promote emotional well-being in birds when these are provided with adequate thought for the bird's safety and comfort. This leads to the next point:

If the bird is kept outside, is it safe from predators and diseases?

Are there potential disease vectors such as mosquitoes, roaches or rats that can access the bird's cage? If the bird is brought into the house at night, is the food and water removed and replaced to prevent contamination of the cage contents overnight and subsequent exposure to diseases such as sarcocystosis? (Note: Additional husbandry issues are covered in Figs 6.14-6.17a-c.)

Predators such as raccoons are notorious for reaching

into cages and severing legs and wings from parrots.

Does the bird come out of its cage? Is it supervised when out of the cage?

Remember that "supervision" is subjective. Many birds with heavy metal toxicity ingest the inciting material while being supervised. Owners are often adamant prior to the radiographic diagnosis that their bird has no access to metal.

Answers to questions concerning time out of the cage will also help establish the degree of interaction between the bird, its environment and its owners.

Are the bird's wings clipped or is it free-flighted? Is the bird exposed to potentially dangerous situations?

Sinks full of water, ceiling fans, open toilet bowls and sliding glass doors are among the potentially injurious, if not fatal, environmental hazards to which a bird may be exposed.

Different injuries and exposures occur in flighted and non-flighted birds. For example, heavy-bodied birds with severe wing clips are prone to beak and keel trauma. While keel and beak tip trauma may be obvious due to the presence of blood, the dislocation or straining of the quadrate bone and associated muscles may present only as depression and lack of appetite.

Conversely, concussive force to the head is most common in fully flighted birds that fly into glass doors or mirrors, as are ceiling fan injuries, burns from stovetops and drowning from accessible water sources.

Does the bird interact with other animals or birds?

Dogs and many other pets may carry clostridial bacteria normally, while pet birds often develop digestive disorders from exposure to such bacteria (see Chapter 4, Nutritional Considerations, Section II Nutritional Disorders). Also, cat claws and bites may cause penetrating wounds that do not leave obvious external marks but often cause internal damage and/or infection.

Is the bird subject to potential exposure to toxins?

Burning plastic, non-stick cooking pans, cigarette smoke, aerosol sprays or household plants are some of the common substances causing toxicity in pet birds. Additionally, the metal wicks of candles may contain lead. Smoke (including cigarette, incense, candles and barbeque grills) and other strong smells are potentially hazardous to pet birds, and exposure to these should be avoided (see Chapter 31, Implications of Toxic Substances in Clinical Disorders [Figs 6.18-6.24]).

DIET

Underlying many health problems in pet birds is the

common thread of malnutrition. For many generations, bird owners have accepted as fact that seed is a complete diet for birds (Fig 6.25-6.41). This is reinforced by advertising from many producers and vendors of bird seeds. Historically, there has been a lack of readily available information on the deleterious effect of all-seed diets. Birds, as many other animals, often prefer high fat diets. Given a choice between seed, vegetables, formulated diets and fruits, nearly all birds will consume the seed first. Given this preference, it is not surprising to hear many bird owners state, "All he will eat is the seed, so that is all that I give him." Chapter 4, Nutritional Considerations, gives more details on nutrition and nutritional disorders. The reader is urged to study this carefully.

How much food is being consumed?

An important part of history taking is to ascertain not what the owner offers the bird, but more importantly, what the bird actually consumes. The clinician needs to be aware that there are major species differences in dietary requirements. For example, some species may have a higher requirement for fat than others. There is no single diet that is appropriate for all avian species any more than there is one diet suitable for all mammalian species.

In addition to the type of food offered and consumed, feeding practices need to be reviewed. Some birds, even when provided with an excellent diet, will consume an excessive quantity and become obese.

Is the food prepared fresh daily? Are dishes cleaned each day? Does the bird dunk food into its water dish?

This last practice of dunking food creates a nutrient-rich broth ideal for bacterial contamination. Sterilization is not necessary in the healthy home environment, but reasonable cleanliness should be employed.

Does the bird get any treats?

Treats can supply sufficient calories to pet birds that any attempt at weight control is sabotaged. Also, certain foods, such as guacamole dip, are not always perceived by the owner as potentially toxic. Other foods, such as snacks containing excessive sodium, may cause or exacerbate feather-destructive or mutilation behaviors (see Chapter 2, Concepts in Behavior Section III p82).

Are vitamin and mineral supplements being administered?

If so, what are the contents of the supplement and in what form is it provided (ie, in the water or on the food)? Vitamins administered in the water may decrease a bird's water consumption, discolor the urates or feces, and either be ineffective due to dilution and lability, or cause hypervitaminosis if administered in conjunction with vitamin-enriched seeds and/or formulated diets.

Fig 6.14 | Cage with natural perches. This bird's cage is too small to allow for flight. Note that two sources of calcium (mineral blocks) are provided in addition to a formulated diet. This may lead to nutritional imbalance due to excess calcium (see Chapter 4, Nutritional Considerations).

Fig 6.16 | Newspaper is a good substrate if changed daily. The number and character of droppings can be determined readily, yielding information reflecting the state of the bird's health. These "popcorn" droppings are not normal.

Fig 6.17b | Plastic perches with ridges to allow a better grip can be wedged into stainless steel cages. They are easy to clean and sterilize.

Fig 6.15 | Here sand is used as a cage substrate. Note the accumulation of feces and food indicating poor husbandry and potential microorganism overgrowth. Sand can be used but needs to be raked clean often and replaced when dirty.

Fig 6.17a | Cement and sandpaper perches. Sandpaper perches are generally ineffectual and may cause or add to plantar surface abrasion. Overgrown nails are a sign of metabolic disease and require addressing the underlying problem. Sharp nail points are normal and necessary in the wild. Owners often request trimming of these tips to prevent discomfort to their skin. Some blunting may be necessary to prevent trauma to the owner, but the bird will be less stable when perching and the owners must be forewarned of this. In some cases cement perches can work to keep the tips blunted when the proper type, size, texture and placement in the cage is accomplished.

Fig 6.17c | Natural hard woods like manzanita make long lasting perches. However, these do not offer a rough surface on which the birds can clean their beaks, nor is such a hard slick surface the ideal perch.

Fig 6.18 | Some dog and cat flea products can be a danger to birds.

Fig 6.19a | "Hardware cloth" is galvanized iron. The galvanized coating is usually predominately zinc and may also contain lead. While usually safe for non-chewing birds like this Tragopan sp., it is not safe for members of the psittacine family.

Fig 6.19b | Toys are frequently made of polished galvanized metal. Here a magnet is used as a diagnostic tool — if it attaches, the underlying metal is iron. This is a common metal that is galvanized to prevent rust. Galvanization is primarily zinc. The circular shaped magnet has attached to a chain and anchor screw, indicating galvanization is likely and these objects should be removed.

Fig 6.19c | Toys can have the galvanized hook replaced with brass, the chain replaced with stainless steel, leather or natural fibers (hemp, sisal or cotton), and the link replaced by one of stainless steel.

Fig 6.20 | A decorative palm tree is a safe house plant but items in the soil such as fertilizer beads and other slow release items can be toxic.

Fig 6.21a | Lead weights used to balance car tires and sink fish bait. These are extremely toxic, being rapidly dissolved in the ventriculus and absorbed into the blood stream.

Fig 6.21b | Curtain weight made of lead.

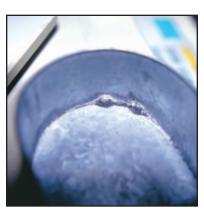

Fig 6.21c | Lead soldered galvanized water dish.

Fig 6.22 | A dangerous toy's clip has gotten stuck on this African grey's beak.

Fig 6.23a | While tobacco can be toxic if ingested, smoke from cigarettes is the product's greatest danger to birds. Contact with nicotine has been considered as a cause of dermatitis.

Fig 6.23b | Shelled nuts often get rancid unless refrigerated or stored in glass or foil bags.

Fig 6.23c | Seeds infested by insect larvae that hatch often become "webby" due to a fungus (usually Aspergillus) and can produce mycotoxins. Do not freeze webby seed and then feed it. The larvae from a grain moth has penetrated this sunflower seed.

Fig 6.23d | Chocolate contains dangerous levels of theobromine and caffeine. Chocolate containing less sugar generally contains a higher level of toxic substances.

Fig 6.23e | Although pothos is considered poisonous in small animals, it has never been a proven cause of systemic toxicity in healthy pet birds.

Fig 6.24 | Mineral blocks, especially when provided to birds on formulated diets, could add toxic levels of calcium (see Chapter 4, Nutritional Considerations).

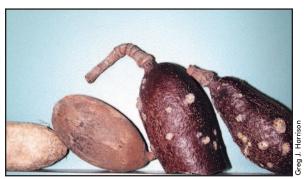

Fig 6.25 | Palm nuts are eaten by wild hyacinth macaws. Cattle consume and digest the sticky, fleshy outer coating. The seed on the left has been passed out in feces; birds prefer to eat the nut in this form.

Fig 6.27 | Offering excessive amounts of unbalanced foods allows the bird to choose its diet and nutritional disorders result. The amount of food shown was offered twice a day. The immature corn (sweet corn), baby beans, zucchini, and squash are of little nutritional value. The broccoli, kale and carrots are difficult to digest. While no sunflower seeds are offered, safflower is just as imbalanced, being even higher in fat than sunflower seeds. Peanuts are also high in fat, and when fed without the shell, often become rancid. Peanuts are a common source of mycotoxins. If they are fed at all, a human grade of peanuts certified free of mycotoxins should be used.

Fig 6.29a | Sunflower seed, millet and canary seed are the historic staples of the bird food industry. Only one current manufacturer of formulated diets uses these century-old ingredients and improves their nutritional balance with appropriate additives. This has improved acceptance and avoided potential problems that one may get when attempting to incorporate novel ingredients. New, untested ingredients can create unforeseen problems that may take decades to discover.

Fig 6.26 | Animal protein (meat, egg, cheese) has been removed from pet bird diets for 15 years with excellent results. Whether adding scientifically formulated amounts of animal protein to the diet of breeding birds is warranted is still unknown. Vegetable protein diets have been empirically proven to be sound.

Fig 6.28 | An aviculture diet used commonly in the 1980's. Birds on sunflower seeds, apples, oranges, grapes, pound cake and bread rapidly developed nutritional disorders, especially the breeding females. Nutritionally deprived parent birds were unable to raise their young. Incubation of the eggs and hand-feeding from hatching had to be employed. The associated developmental problems in the young disappeared when a formulated diet was instituted.

Fig 6.29b | Since no standards have been officially declared, diets such as the one pictured above are incorrectly marketed as "complete diets" in many pet stores. Colored seed is the largest part of the pet bird food market in the USA. Newer versions of these colored seed diets have added shaped and colored pellets but empirically are not nutritionally superior to plain seeds.

. Harrison

Fig 6.29¢ | A scarlet macaw taken from a USA pet store magazine ad for a product that claims to have been developed by their researchers "to make a new all natural... treat (sic) premier supplement for all caged birds — and better than all other brands." The abnormal color and physical characteristics of the bird's feathers would indicate the company, their researchers and/or advertisement personnel are uninformed as to the desired physical attributes of a healthy bird.

Fig 6.29d | Free-ranging scarlet macaws hand-raised on an organic formula in Tambopata, Peru. Notice the tight feather structure and brilliant colors compared to Fig 6.29c.

Fig 6.30 | An aviculturist's food bowls for macaws and large cockatoos on the left and Amazons and African greys on the right. The organic formulated nuggets are a high potency formula. During the non-breeding season the seeds and nuts are stopped and for some species the nuggets are changed to a maintenance product. After ten years of this diet, the common avicultural problems of infertility, incubation, raising, hand-feeding from day one, congenital and developmental conditions and chronic "infections" are no longer encountered. The parents incubate and raise the babies until a week or so prior to weaning, when hand feeding is initiated to assure tameness. With production increased and problems decreased, profits at this aviary have soared.

Fig 6.31 | Twenty-five grams of whole grain (dense) organic nuggets (on the right) compared to an equal weight of traditional extruded brand made from refined flours that expand more readily. The fiber and other ingredients in whole grain flours lack the refined carbohydrates necessary to get the extrusion-induced expansion (fluff) attained with extrusion of these less-nutritious refined flours. These less expensive refined flours are by-products of the oil industry. The end product produces larger, lighter bags of food at a reduced cost. Such products require more additives than whole grains to establish balanced nutrition.

Fig 6.32 | Quantity of pellets consumed in a day by a cockatiel for \$.01 (USA). Many owners waste food as they are not properly educated on proper food volumes.

Fig 6.34 | Seeds top-dressed with a powdered mineral/vitamin supplement show the powder on the bottom of the food cup, which is subsequently disposed of with the seed hulls.

Fig 6.36 | Organic formulated nuggets are low in synthetic vitamins and have natural sources of nutrients (alfalfa and spirulina for carotinoids, kelp for iodine and trace minerals, sea salt, natural clay with naturally chelated minerals, high soluble fiber from digestible hulls and psyllium). These nuggets are free of pesticides, food coloring, by-products and preservatives. The absence of preservatives requires cool, dry, dark storage in airtight containers to prevent rancidity or loss of nutrient value (see Chapter 4, Nutritional Considerations, Section II Nutritional Disorders).

Fig 6.33 | While many theme parks' cage labels state that the birds eat a formulated diet, the bowls are often full of a seed mix with colored pellets. Nutritional disorders are commonly observed in such a facility. Incentives such as free foods, cash donations and revenue sharing may be given to the facility for reciprocal endorsements that have little to do with the actual food fed or its nutritional value.

Fig 6.35 | Veterinarians in the USA often recommend a pressed seed cake. The waste in this bird's cage shows that most has been discarded except for the oat hearts. The food coating (egg, minerals, and vitamins) was discarded untouched. This bird had liver, respiratory and orthopedic problems that improved when switched to an organic formulated nugget that could not be selectively consumed.

Fig 6.37 | Vitamins in this bird's water color it yellow. Many birds will not drink freely from water with this color and taste, and dehydration can result. Bacterial and fungal growth is also encouraged in this medium. Finally, the dilution of the vitamins and exposure to water, air, heat and light degrade many of the labile vitamins.

Fig 6.38 | Water is often contaminated by improperly designed purifiers. Many allow bacterial proliferation or fail to remove pollutants. In the USA, reverse osmosis (blue and white canisters), bottle and tap water are commonly provided. Only water labeled "USDA drinking water" is regulated and must meet government standards.

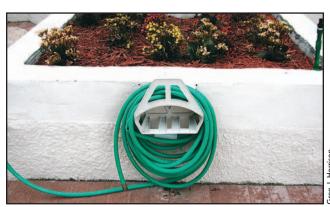

Fig 6.39a | Plastic pipe and water hoses have been incriminated in chronic *Pseudomonous* spp. infections.

Fig 6.39b | Inadequately cleaned plastic bowls are potential sources of bacterial infections. Crock and stainless steel are less porous and thus less likely to be a problem. Water bottles are best constructed of non-porous glass.

Fig 6.40 | Salt/mineral spool, mineral block, powdered calcium, grit and oyster shell are not necessary for birds fed formulated diets, and can be harmful (see Chapter 4, Nutritional Considerations).

Fig 6.41 | Male cockatiel on a seed and table food diet. Note the bent tail, ruffled feathers, and excessive pin feathers over the shoulder and crown. The same bird is shown in Fig 6.3a 6 months after conversion to an organic formulated diet.

Pediatric Patients

Concerns with babies still being hand-fed add additional elements to the anamnesis.

What hand feeding formula is being used? Is the formula being prepared according to the manufacturer's recommendations? Is anything extra being added to an already balanced diet?

It is common to see a hand-feeding formula designed for macaws used on a baby Cacatua spp., with resultant hepatic lipidosis. Likewise, additives such as peanut butter, macadamia oil and sunflower seeds can add additional fat and detract from other necessary nutrients.

Conversely, many prepared formulas for hand-feeding have insufficient calories per unit volume for some species of psittacines, notably macaws.

What is the temperature of the food when fed? What are the quantity, frequency and method (syringe, tube, spoon, cup, weaning pellets) of feeding? Using a microwave to heat the formula can lead to crop burns. What is not commonly understood is the following: food heated in a microwave oven can have hot spots due to uneven heating. When water is heated in a microwave oven and then poured into another container to be mixed with the formula, the temperature of the resulting formula will be more uniform. The temper-

ature of the formula should still be accurately assessed

with a thermometer.

However, if the same container in which the water is heated is used to receive the powered formula, and multiple syringes are extracted over several minutes from this container, disaster often occurs. Many containers hold heat from the microwave, and gradually transfer this heat into the formula, causing the subsequent syringes that are delivered to be much hotter than the initial temperature reading indicated. Severe crops burns can result from this practice.

Conversely, baby birds may refuse formula that is not warm, and cold formula can delay crop emptying.

Various methods of administering the formula are used. Most common still is the use of a syringe, which allows an accurate determination of the quantity of formula being consumed. Spoon and cup feeding are also used successfully by some. Soft plastic or rubber tubing can be used, and this method does decrease the mess produced by bobbing, but carries the inherent risk of accidental ingestion of the tube if it becomes detached from the syringe. It also may not be as psychologically satisfying as having food that can be tasted.

The use of soft, warm, solid foods for feeding and weaning is advocated to more closely approximate the natural feeding patterns of these birds. This technique has been extensively used by Phoebe Linden, of Santa Barbara Bird Farms, with promising results.

Inexperienced hand feeders often cause aspiration or inadvertent starvation of birds while hand feeding. Generally, a baby bird can accept roughly 10% of its body weight per feeding. The frequency of the feedings and the quantity of each feeding will vary with the age, species and individual.

Common problems to look for in the history and physical examination of hand-feeding baby birds include:

- 1. Insufficient calories being given. Often a new bird owner will adhere to guidelines that state a bird should have a reduced number of feedings per day at a given age. The owner may fail to understand that this is based on the supposition that the bird is starting to eat on its own at this age. Some birds have not yet even been offered food, but the frequency of feedings has been severely reduced, leading to weight loss and debilitation.
- 2. Over-distention of the crop. This can have many causes, but over-distention may be obvious on physical examination and may be associated with a history of feeding an excessive volume at a given feeding.

BEHAVIOR

A behavioral history is becoming increasingly important as pet birds move out of their cages and into their owners' lives. Just as countless dogs and cats are euthanized every year because of behavioral problems, many birds suffer a similar fate or are transferred from household to household.

As psittacine behavior is determined largely by the interaction between the bird, its owners and its environment, questioning must focus on these areas. Who is the primary caretaker? Whom does the bird seem to prefer? Does the bird dislike anyone? How many hours per day does the bird spend alone? What does the bird see and hear when it is alone? Does the bird spend time with other birds or other pets?

Many factors that may influence pet psittacine behavior are yet to be determined. For example, recent work has indicated that fluorescent lights are perceived as a constant flickering by the eyes of birds, and both physiologic and behavioral problems may arise from previously unrecognized sources such as these. Also, there is increasing concern that our traditional methods of handfeeding may by laying the groundwork for the development of behavioral problems later in life (see Chapter 3, Concepts in Behavior).

It is important to clarify the bird's interaction with its

owners (human flock). How tame is the bird? Does it readily step up onto a proffered hand? Does it always try to move up onto a person's shoulder? Is this allowed or encouraged? Does the bird talk? Does it like to be petted? Where? How does it react to different family members? How does it react to strangers? For the potential significance of the answers to these questions, see Chapter 3, Concepts in Behavior.

The Presenting Complaint

Once the bird's background has been established, it is time to assess the reason(s) the bird has been presented. Ask the client to describe the problem. Do not interrupt the client other than to seek clarification of details. You may need to repeat back to the client what they have said to ensure that a mutual understanding and clarification of the owner's concerns are reached. For example, many birds presented by their owners for "diarrhea" are actually polyuric. An explanation of the difference between diarrhea and polyuria, and a determination of which is actually present, should be made prior to the physical examination and diagnostic testing.

Once the practitioner has identified the problem(s), appropriate questions must be asked of the client to determine duration, severity, progression, previous diagnostics if known, previous therapeutics, and response to prior treatments. When did it start? Is this the first time it has happened? Have other treatments been tried? Who prescribed these treatments? Did they work? Is this condition static, progressive, or resolving? Are other birds affected?

The history taking as described above is not comprehensive. As one gains information, areas of concern will become apparent, and additional questions may be needed for clarification. The clinician must not dominate the conversation — rather, he or she should ask short questions and listen carefully to the client's reply. However, the clinician must be prepared to guide the discussion, to ensure that the maximum amount of useful information is obtained.

The Distant Examination

During the history taking, the clinician should be observing the bird and noting its behavior prior to restraint.

Most birds, no matter how ill, will make an effort to mask their clinical signs when first brought into the examination room. The clinically ill bird will be unable to maintain this pose for any length of time. Avoid disturbing the bird until it has settled, otherwise valuable clinical signs may be overlooked. The practitioner should be seated in order to remove any predatory threat to the bird. This will expedite its relaxation and therefore accelerate the demonstration of clinical signs.

Observe the bird's respiration (Fig 6.42a). Once the bird has settled in its cage in the examination room, there should be no open-mouthed breathing, marked tail bobbing, increased respiratory effort or audible respiratory noise. The presence of these signs should alert the clinician to potential respiratory compromise. Respiratory compromise may be due to true respiratory disease, cardiac disease, space-occupying mass or fluid within the coelom, anemia or severe debilitation. Care must obviously be taken with handling patients that are demonstrating respiratory distress.

The bird's posture should be observed (Figs 6.42b-d). Sick birds that are hypothermic will fluff their feathers in an attempt to conserve body heat. They sit still to conserve energy and, as they weaken, they sleep more (Fig 6.42e). Such signs are the classic "sick bird look," but not all sick birds will display these signs.

Evidence of a wing droop, lameness or reluctance to bear weight on one leg may indicate a musculoskeletal problem or a central or peripheral neurologic affectation. Spinal deformities can often be detected by an abnormal positioning of the tail. An upright position with a wide-legged stance may indicate egg binding or a similar space-occupying mass in the coelom or cloaca. Birds that hold both wings away from their body and pant are usually heat stressed or severely oxygen deprived.

The bird's plumage can be cursorily examined prior to restraint. Normally the plumage should be sleek, well groomed and clean. Untidy or dirty plumage may indicate that the bird is not grooming itself, or that there is some type of feather abnormality. Discolored feathers can reflect a variety of problems, including PBFD, chronic liver disease, excessive handling with oily hands or malnutrition. Closer examination of the feathers is warranted when the bird is removed from its cage.

Note the condition of the beak and toenails. Overgrown or flaky beaks or overgrown and twisted nails may be associated with PBFD, poor husbandry, chronic liver disease or malnutrition.

Watch as the bird defecates, looking for signs of straining or discomfort and listening for any accompanying flatulence or vocalization. Birds do not generally pass any gas and should be able to defecate effortlessly.

Observe the bird's behavior, assessing how tame the bird

Fig 6.42a | Prior to handling this dyspneic female cockatiel oxygen is warranted (see Chapter 7, Emergency and Critical Care).

Fig 6.42c | The same bird as in Fig 6.42b is shown preening. Physical exam demonstrated an egg in the reproductive tract. This exemplifies the ability of a bird to mask symptoms.

Fig 6.42e | This finch (or any bird that is motionless and on the bottom of the cage) is a high risk patient. The clients need to be informed in advance of the danger of handling such a sick bird. Heat and oral electrolytes, glucose and caffeine are often the best first steps. The prognosis for such birds is guarded, and a simple breast muscle evaluation will determine if emaciation is present. This commonly encountered finding confirms the chronicity and severity of the bird's condition (see Fig 6.2c).

is and whether it is showing any overt sexual display towards the owner, objects in its cage or other people present in the room. Note the owner's interaction with the bird, as this may reveal valuable clues to relationships at home.

Fig 6.42b | The owner noted that this pearl female cockatiel was fluffed and not eating its seed diet.

Fig 6.42d | A 20-year-old lutino cockatiel is shown after having the jugular vein wet with alcohol for venipuncture. At this age, geriatric considerations are pertinent. Even this minor restraint has caused the bird to appear listless and sleepy. Geriatric (or otherwise stressed) birds may require more gentle handling and for shorter periods of time. Geriatric birds may benefit from the addition of fatty acids and herbs to the diet (see Chapter 10, Integrative Therapies). Geriatric pet birds are becoming more commonly seen in practice.

THE CAGE

The cage must be of sufficient size to allow the bird to extend and flap its wings and to turn around without damaging feathers. The bird should ideally be able to express its normal behaviors within its cage, unless the cage is used only as a roosting space while the bird has access to a larger environment. The cage should be constructed of materials that are safe and appropriate for the size and power of the bird's beak. Small gauge wire, while suitable for smaller psittacines, is readily chewed and eaten by larger birds, often leading to heavy metal toxicity. Similarly, poorly galvanized cheap wire often has tags of zinc on it that are easily picked off and swallowed by psittacines of all sizes. Unsealed wooden cages are inappropriate, not only because many birds will chew the wood, but also because wood is impossible to disinfect, making it difficult to maintain adequate hygiene.

The floor of the cage should not be covered with grit, sand or wood shavings. The substrate of a cage is rarely changed with sufficient frequency, and ingestion of substrate material can lead to blockage of the gastrointestinal tract. Newspaper is a non-toxic and readily available substrate. It is also inexpensive, which encourages frequent changing.

Many cages are sold with plastic or wooden dowel perches. These are rarely suitable, since the smooth, unchanging surface and diameter offer little exercise for the feet and toes, and the symmetry can create constant pressure on selected areas of the feet, leading to pododermatitis. The uninformed owner may be reluctant to discard these perches, assuming that since they were supplied with the bird cage that they are appropriate. Just as variation in diameters and surfaces of perches are important for the individual bird, birds of various sizes and species require different ranges of perch diameters.

The positioning of the perches within the cage is also important. Birds tend to sit on the higher perches, so the diameter and texture of these perches may need to be alternated. Perches should not be placed so that a bird will be defecting into its food or water dish. A bird may be encouraged to sit on a concrete perch if a food dish or treat cup is placed so that access to this cup is achieved by perching on the desired surface.

Dishes should be constructed of a material appropriate to the species using them, and free of contaminants such as lead, which has been used as a solder to repair cheap galvanized dishes. Galvanized dishes should not be used, as the zinc in the galvanized coating may leech into the food or water. Dishes should be cleaned daily and positioned where they are unlikely to be soiled. Food and water dishes should not be placed alongside each other, as many birds will drop their food into the water, producing a broth within a few hours. Birds that tend to dunk their pellets into their water may need to have the water and food dishes placed on opposite sides of the cage.

Toys should be appropriate for the bird, and should not be so numerous as to restrict the bird's movement within the cage. Cheap toys, especially bells, are a common source of lead or zinc. Metal items that can be attached to a magnet are iron based. Shiny silver-appearing metals are often galvanized and polished and are a potential source of zinc toxicity (see Figs 6.19a-c). Toys should be made of natural materials, such as rope and wood, and should be replaced as soon as they become frayed. Bathing or misting should be available on a regular basis (see Chapter 3, Concepts in Behavior).

ODORS

Birds that are exposed to significant cigarette smoke will absorb the odor of smoke onto their feathers. Problems ranging from respiratory disease to feather destructive behavior have been linked to excessive exposure to smoke.

The feces of birds with enteritis, especially due to clostridial species overgrowth, have a distinctive, fetid odor. This seems to be most prevalent in cockatoos with fecal retention and cloacal prolapse and in birds with extensive and restrictive cloacal papillomatosis, although it may occur in any bird. The detection of this odor in a bird's stool should be pursued diagnostically, usually by first performing a Gram's stain on the feces.

Owners may present their bird, commonly an Amazon, for "bad breath." This is usually the natural smell of these species, and not related to disease.

Examination Room Equipment

Appropriate equipment for use in the examination room includes:

- A supply of freshly laundered towels of different sizes (or paper towels) for restraining birds.
- Scales capable of weighing in grams, preferably with a detachable T-perch (to allow birds to perch on while being weighed), and a container in which to weigh smaller, fully flighted birds.
- A training perch for the bird to perch on while being examined.
- Clinical equipment, such as stethoscope, a focal light source, magnifying loupes, needles and syringes, blood collection tubes and culture swabs.

The use of heavy gloves to catch and restrain birds should be discouraged. With these gloves on, the clinician cannot be sensitive to small movements of the bird, and can easily hurt or even kill the patient. Additionally, these gloves cannot be cleaned or sterilized.

Ensure that the room is escape proof, and that clinic staff will not enter the room unexpectedly. Avoid stressful sights and sounds such as dogs, cats and other potential predators.

Handling and Restraint

Once a thorough history has been obtained and the bird observed in its cage, the next step is to examine the patient more closely. In order to do so, the bird will

need to be handled and restrained. In the case of aviary birds, this should be done with a view of minimizing stress to the bird, while at the same time, avoiding injury to the handler. Many companion birds, on the other hand, have learned to trust humans and regard them affectionately. Destroying this trust through aggressive catching and handling techniques can adversely affect the bond between owner and bird. This relationship must be preserved, and handling techniques for closely bonded birds should emphasize minimal stress and fear (see Chapter 3, Concepts in Behavior).

As the oils on human skin can be detrimental to the feathers of many species, a light dusting of unscented talcum powder on the clinician's hands is appropriate before beginning an examination.

Be aware that the scrubs or other clothing worn by the technicians and practitioner will be exposed to powder down and fecal material during handling and restraint. The potential for disease transmission to subsequent patients should be considered and clothing changed when appropriate.

By the time the clinician is ready to examine the bird, the general temperament of that bird should have been established. If the cage is the bird's home, its territorial instincts may drive the bird to protect its cage from the intrusion of strangers. In many cases, therefore, it may be appropriate to ask the owner to remove the bird from the cage. If the owner is unwilling (or unable) to do so, the clinician should study the cage to determine the best means of removing the bird. Tame birds may simply step through an open door. At other times, the cage may need to be dismantled rather than trying to catch and remove a bird through a small door. If the bird is friendly, the clinician should gently introduce a hand into the cage, with the back of the hand to the bird. If there is no aggression, the forefinger is extended and placed under the bird's chest. A tame bird will usually step onto the finger. Restrain the foot or a toe by gently pressing on it with a thumb against the finger, keeping the bird steady, and gently bring it out of the cage. During this procedure, the clinician should be talking to the bird, praising it, and maintaining eye contact. Once the bird has been removed from the cage, continue to praise it and, depending on the species and individual, scratch its head, its axilla, or simply continue talking to it while raising it to a height at which it appears comfortable. If the bird has to be physically caught, it is usually best to use a small hand (or paper) towel to gently envelop and then restrain the bird. Show the bird the towel and let it become accustomed to its appearance. If possible, the clinician should envelop the bird in the towel from below — an approach from above

is potentially a very intimidating experience for a pet bird. Keep talking in a friendly voice, and maintain eye contact (see Chapter 3, Concepts in Behavior).

Birds that are not tame can be caught using a towel as described above. These birds will rarely stay still during capture, so a quick capture is the best approach. The most dangerous part of the bird's body should be immobilized first (ie, psittacines = the head and beak; raptors = the feet). Once the dangerous areas are immobilized, the bird is wrapped in the towel and removed from the cage.

When the bird has been removed from the cage, the next step will be determined by the bird's tolerance of handling. Very tame birds can be placed on scales to be weighed, while less tame birds may need to be examined first while still restrained and weighed just before being returned to their cage.

At all times the clinician must be aware of the bird and how it is handling the stress of restraint and examination. Many birds are presented for evaluation of an illness, having been ill for a period prior to the owner's recognition of disease, and the stress of restraint can exceed their ability to compensate. Collapse and death are, unfortunately, not uncommon with critically ill birds. If there is any doubt as to the bird's ability to cope with the stress, it should be immediately returned to a perch or the cage and allowed to regain its composure before proceeding. Critically ill birds should not be handled initially (see Chapter 7, Emergency and Critical Care).

THE "PUT IT DOWN" LIST

Panting and increased respiratory rate while being examined warrant attention. It may be that these are normal compensation techniques for a stressed or obese bird, but during restraint, it is difficult to determine the extent of the stress without reducing the effectiveness of the restraint.

- 1. If the bird is panting or breathing rapidly, first alter the grip on the head so the head is free to move. The bird should immediately begin to turn its head in search of something to bite. If it doesn't, PUT IT DOWN.
- 2. A paper towel or a corner of the towel being used to restrain the bird can be placed into its mouth. It should immediately begin to bite at this, demonstrating that it has sufficient oxygen reserves to do so. If the bird lets the material lay limply in its mouth, PUT IT DOWN.
- 3. Have the bird grasp your hand or finger with both of its feet. (This should be part of the physical exam anyway, to determine symmetry and strength of grip). If the bird's grip is weak or non-existent, PUT IT DOWN.
- 4. If the bird's eyes close during the physical exam, PUT

Fig 6.43 | Disposable paper bags provide a dark area for restraint for all but the largest of birds. This can be used to obtain a body weight on untamed birds.

Fig 6.44 | For birds that will perch a digital scale with an easily disinfected perch stand is ideal. In this case, the wooden perch is coated with an epoxy sealer.

IT DOWN. Conversely, do not be reassured if the bird has its eyes open — many birds have held their eyes open as they drew their last breaths.

5. If in doubt, PUT IT DOWN. Return the bird to the location (cage, owner) where it is most comfortable, and observe it while talking to the owner.

The Physical Examination

"You will miss more by not looking, then you will ever miss by not knowing."

The old veterinary adage expressed above is as true for avian medicine as it is for any other species. A thorough, systematic physical evaluation of the patient is essential to obtaining information regarding the bird's problem and diagnosis. Clinicians should develop a thorough examination protocol with which they are comfortable, and use it for every (stable) patient, regardless of the reason for presentation. A physical examination form may be useful in ensuring that nothing is overlooked.

BODY CONDITION

All birds should be weighed during each visit to the veterinarian, and at the same time each day while hospitalized. Monitoring an individual bird's weight will often detect potential disease prior to the demonstration of clinical signs. The veterinarian will also develop an appreciation for the normal body weight ranges of various species. The weight should be recorded in grams, as this allows accurate monitoring (Figs 6.43, 6.44).

Traditionally a bird's body condition was determined by palpation of the pectoral muscles and allocating a body score based on the muscle and fat coverage of the sternum. Although useful as a cursory determination of emaciation, this technique fails to take into account that most birds do not store fat in their pectoral region and can be carrying significant fat deposits while still having an apparently normal body score. Wetting the feathers over the abdomen, flanks, thighs and neck with alcohol allows visualization of subcutaneous fat deposits, seen as yellow fat under the skin rather than pinkish-red muscle (Figs 6.45α,b-6.47α,b).

The combination of body-weight recording, pectoral muscle palpation and examination of subcutaneous fat allows an accurate assessment of body condition.

BLEEDING

Bleeding or bruising may be encountered during or produced by the physical examination. Excessive, prolonged or abnormal bleeding or bruising in birds is often related to one or more manifestations of malnutrition. The following is a brief list of the most common presentations and associated etiologies:

- Conjunctival hemorrhage or "red tears" are commonly seen in African greys and Quaker parakeets (see Fig 6.47a2 for information on potential etiologies).
- Denatured blood in the nasal debris of psittacines.
 This seems particularly prevalent in mutation cockatiels (see Fig 6.47b2). Malnutrition causing squamous metaplasia and secondary bacterial and fungal infections is a likely cause in many birds. In these cockatiels, however, there may also be a decrease in

Fig 6.45a | Body condition scores on simple pectoral profiling are not accurate. This blue and gold macaw is 1300 g and has cleavage in the area of the keel's carina. When the bird's feathers are wetted down with alcohol, no fat in the sub-cutaneous tissues is evident. However, on the commonly proposed body score technique, this bird would be called obese because the breast muscle exceeds the keel's carina in depth. Obese birds are considered high risk birds. This is a large blue and gold, but it is not obese.

Fig 6.45b | Same bird as in Fig 6.45a at a distance. Note the appearance of the feathers. They appear as a unit, not a collection of individual feathers. The colors are clear and crisp. The feather margins are smooth and sharp. The feathers are strong and straight. The skin is reptilian and boldly patterned. The nares, facial skin, eyes and nails are all exemplary. Max has been on a high fat organic formulated nugget for 10 years with limited fruits and vegetables. Natural sunlight and showers are frequently provided. Note the lack of flaking or layering of the beak. No flaking is present on the facial skin and no debris has accumulated in the nares.

intrinsic clotting factors. Verification and etiology of this coagulopathy have not been determined, but malnutrition and hepatopathy, as well as genetic predisposition, should be considered.

- · Facial skin bruising is often noted in macaws and African grey parrots (see Fig 6.47c2). This can be the result of restraint that is too aggressive or an inherent bleeding dyscrasia. The same condition likely occurs in other species, but the presence of feathers in the periorbital area prevents observation of the bruising. Malnutrition is likely to be the major underlying cause of overly fragile dermal tissue and decreased coagulation factor production.
- Beak injuries (Fig 6.47d2).
- Broken blood feathers (Fig 6.47e2).
- Blood from the cloaca.
- Blood in the urine.
- Bite wounds (Fig 6.47f2).

PLUMAGE

Normal feather development in a baby cockatoo is shown in Figs 6.48a-g. Normal adult feathers are seen in Figs 6.49-6.56a-e and Chapter 2, The Companion Bird.

Attention should be paid to the following areas (Figs 6.57a-z-6.59c):

- Color of the Feathers. Abnormal coloration of feathers can be due to a multitude of causes. PBFD can cause green feathers to turn yellow and blue feathers to turn white. It will also lead to a generalized dirtiness of the feathers, especially in cockatoos. Chronic liver disease and/or malnutrition can cause darkening of feathers and a decrease of powderdown production in applicable species. Frequent handling of birds by the owner can leave a deposit of oil on the feathers, which then encourages fungal overgrowth. This causes a black discoloration on these feathers. This is not seen in birds with powderdown, presumably because the powder keeps the feathers clean.
- Tidiness of the Plumage. Birds generally keep their plumage well groomed and tidy. If the plumage is untidy, with no immediately obvious cause (eg, recent handling), the clinician should suspect that either the bird is unable to groom itself properly, or a generalized feather dystrophy (eg, PBFD) is present.
- Evidence of Feather Damage. Chewed and/or broken

Fig 6.46a | Alcohol can be used to part the feathers to ascertain the absence or presence of body fat. This bird has an accumulation in area three (the abdomen, just anterior to the vent). Other areas should be observed.

Fig 6.46b | This young budgerigar has a bulging fat mass at the furculum (area one).

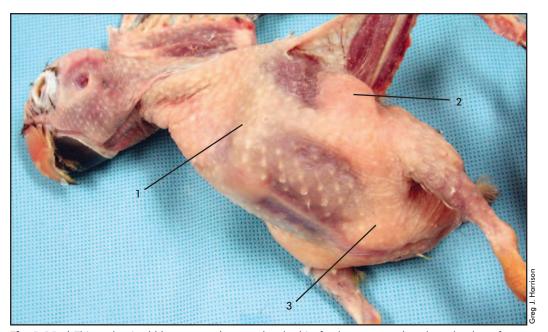

Fig 6.46c | This euthanized blue-crowned conure has had its feathers removed to show the three fat areas coalescing. 1 is area one. 2 is area two. 3 is area three. Area two, the axilla, is still discrete. Note the fat is deposited subcutaneously to the feather tracts.

Fig 6.46d | Dorsal view of bird in 6.46c. Fat depositions continue in feather tracks over the wing, scapula and pelvis.

Fig 6.47a | A very ill conure is barely able to keep its eyes open and maintain its balance. Despite the presence of strangers it remains fluffed during clinical presentation. This implies a grave prognosis.

Fig 6.47a2 | Quaker (monk) parakeet with a drop of conjuctival blood post-examination. This phenomena is commonly observed in African greys when restrained. A nutritional disorder is usually involved. Subclinical rhinitis and sinusitis have been incriminated in this production of bloody tears from conjunctival hemorrhage, Squamous metaplasia of the respiratory system is likely underlying the respiratory disease. The degree of blood pressure elevation that restraint creates may also be a factor in more sensitive species (see Chapter 4, Nutritional Considerations).

Fig 6.47c2 | Facial erythema and subsequent scabs like those shown in this African grey are often seen in macaws following restraint. While the immediate cause is the handling, the underlying skin fragility usually responds to nutritional correction.

Fig 6.47b | Same conure as in Fig 6.47a. When the feathers are wet with alcohol, there is obviously little remaining breast musculature. This severe emaciation carries a grave prognosis. Handling such a bird without ascertaining its tolerance for restraint via proper distance observation will often precipitate a crisis. If the bird dies, the crisis will be with the owner. The owner will assume the bird died due to inappropriate veterinary care. Proper evaluation can avoid such a crisis. Most birds in this condition will not survive, but a few, when gradually and cautiously approached with treatment and diagnostics, will respond. In either case, the owner must be informed in advance of the severity of their bird's condition.

Fig 6.47b2 | Cockatiel with black rhinal discharge that is hemoccult positive. Secondary invaders are common and often require therapy. This therapy often includes nutritional correction.

Fig 6.47d2 | Budgerigar with beak bleeding after trimming. A nutritional disorder is likely. Budgerigars and other parrots do not normally require beak trimming. The vessels in a nutritionally imbalanced bird's beak grow closer to the tip and bleed more profusely. Styptics will usually control the bleeding.

Fig 6.47e2 | Mealy Amazon with a fractured primary remige. Pulling the feather is no longer recommended. Damage to the delicate structure of the feather follicle (see Fig 6.56c,e) may occur. Clip off the distal portion and apply baking flour to the stub until bleeding stops. Birds that bleed excessively may respond to injections of vitamin K. Nutritional disorders need to be addressed. In a well bird the feathers are less likely to fracture and if they do, the subsequent bleeding is generally self-limiting.

Fig 6.47f2 | According to the owner, this lovebird was mouthed but not bitten when "picked" up by their dog. Wetting feathers to examine for hematomas associated with tooth penetrations is an easy technique. The owner's assumptions were proven wrong in this case and antibiotics are indicated.

feathers should lead the clinician to suspect overgrooming, self-mutilation, cage mate trauma or malnutrition. Saw-toothed edges can indicate a failure to molt normally; hence, old, worn feathers are being retained. It should be noted in cases of feather destructive behavior, whether the feathers have been bitten off level with the skin, plucked out, or if the shaft is being chewed.

- Evidence of Feather Dystrophies. Retained feather sheaths, retained pulp, hemorrhage in the shaft of feathers, strictures of the calamus and twisted feathers are indicative of feather dystrophies, often of nutritional, genetic, traumatic or viral origin (ie, polyomavirus, circovirus).
- Wing Clipping (if present). The wings should be examined to determine if the bird's wings have been clipped and, if so, if that clip is appropriate to the species and temperament of the bird. The degree of lift that the bird is achieving with the current clip should be determined by asking the owner and by a "test flight" in a safe area, if needed. The owner's satisfaction and the effectiveness of the last clip should be determined. The clip should be examined to determine if the cut ends of feathers could be bothering the bird.
- Absence or Presence of Powder Down. Powderdown is produced by the powderdown feathers on the thighs of many species of birds, particularly cockatoos and African grey parrots. It is easily recognized by the presence of a fine white powder on the clinician's hands and clothing after handling the bird. A lack of powderdown leads to staining of the feathers and a shiny appearance to the beak and feet. The most common causes of loss of this powderdown include: malnutri-

- tion, hepatic disease, genetic mutations (notably in cockatiels) and circovirus in *Cacatua* spp.
- Molting Patterns. Most birds will molt heavily twice yearly, in spring and autumn the so-called "prenuptial" and "post-nuptial" molts. Outside of these annual molts, there is a steady and progressive turnover of old feathers. The end result in psittacines is that each feather is normally replaced once a year. Continual heavy molts or the sudden loss of many feathers is abnormal, as is the failure to molt (seen as the retention of worn and broken feathers).
- The Presence of Stress Lines or Stress Bars. Stress or disease at the time a feather is growing will lead to a transverse "break" in the vane of the feather. The presence of many feathers with such stress lines is indicative of a problem in the bird's recent past.
- The Condition of the Skin. The presence of erythema, excessive scale or areas of skin trauma should be noted. This can be done by parting the feathers with a cotton-tipped applicator, or gently blowing on the feathers.
- Areas of Trauma. The skin should be thoroughly examined for areas of trauma, especially on the wing tips, sternum, cere, ventral pygostyle and axillae.
- Flexibility of the Feather (Figs 6.58a-c). The shaft of the feathers of a healthy bird on a good diet should flex rather than break when the tip is drawn down towards the base; the feather should spring back to a normal position when released.
- **Parasites.** The presence of parasites on the feathers should also be noted; microscopic examination may be necessary for detection (Figs 6.59a-c).

Fig 6.48a | Baby Umbrella cockatoo at day 2.

Fig 6.48b | At 2 weeks of age this bird shows a minor prognathism developing and crooked toes. This was likely a result of the seed-based diet fed to the parents.

Fig 6.48c | At 4 weeks of age. The organic hand-feeding formula has overcome the beak and toe problems.

Fig 6.48d | At 6 weeks of age the slight weakness of the abductor muscles in previous figures has been corrected and the baby is standing.

Fig 6.48e | Eight weeks of age.

Fig 6.48f | Ten weeks of age.

Fig 6.48g | Twelve weeks of age.

Fig 6.49 | A perfectly feathered goffin cockatoo in a defense (attack) posture stimulated by the toy owl.

Fig 6.50 | A Moluccan (salmon-crested) cockatoo displays a greeting feather erection and reaches out with the foot to be picked up. The bird has been fed an organic formulated diet since hatching, 8 years ago. A healthy bird can normally separate its feathers in this manner. Observe the beak, skin around the eye and the feet. Note the strength and vibrance of the feathers. The bird's attitude is upbeat and active. These are some determinations one needs to master in avian medicine. This requires either seeing normal specimens, such as this bird, or transferring in one's mind's eye the characteristics seen in most wild birds. If only seed-eating pet birds are seen in practice, normal is not appreciated.

Fig 6.51 | Two grey-eyed (immature) African grey parrots. Color tones and feather scalloping on these birds are ideal.

Fig 6.52 | This citron-crested cockatoo is normal except for a mild unzipping of the crest feathers.

Fig 6.53a | This severe macaw is showing a defensive posture. The feathers are of poor color and structure. Such feathers often dramatically respond to diet change.

Fig 6.53b | Approximately 1 year later, the bird in Fig 6.53a has been guided by Jan Hooimeijer into the specimen seen here. Owners were instructed in an hour long office consultation on nutrition, husbandry and behavior. The diet was changed to an organic nugget. Periodic evaluations were scheduled to assure secondary problems were not becoming clinically significant. When an avian practitioner has repeatedly seen improvement in these cases with only dietary correction, recommendations for diagnostics in future cases are often altered. A CBC may be warranted to determine if concurrent infection is present. Serum chemistries with bile acids may be performed. However, abnormalities in hepatic enzyme levels, calcium levels and other parameters are often a reflection of the effects of chronic malnutrition. In the absence of clinical disease, the practitioner may elect to institute a wellness program, with the primary emphasis on dietary correction. In this case an organic formulated diet, lactulose and milk thistle were administered. This is a particularly judicious approach if the bird is stable but likely suffering from malnutrition-induced decreased hepatic function. These birds are not ideal candidates for venipuncture due to potential clotting deficiencies. Even more significant, hepatic biopsy, although it may be diagnostic, can be a fatal procedure in the presence of hepatic insufficiency (see Chapter 4, Nutritional Considerations).

Fig 6.54 | A 17-year-old seed-eating cockatiel shows hyperkeratotic follicles, generalized weakness, worn feathers and retained pin feathers.

Fig 6.55 | A wild-caught sulfur-crested cockatoo (Cacatua galerita galerita) which is fed a seed diet, displays poor feathering. Note the fluffed appearance, unzipped crest feathers and its position on the bottom of the cage. The physical examination revealed a retained egg. Malnutrition was addressed over the next few visits.

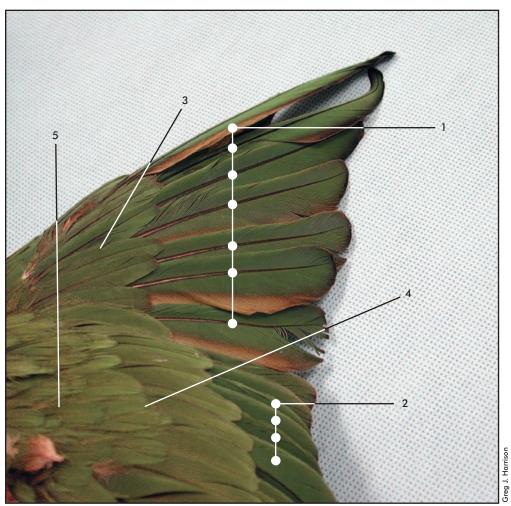

Fig 6.56a | Plumage of the extended right wing. Dorsal view. 1. Primary remiges 2. Secondary remiges 3. Primary coverts 4. Secondary coverts 5. Upper marginal coverts of the propatagium and manus.

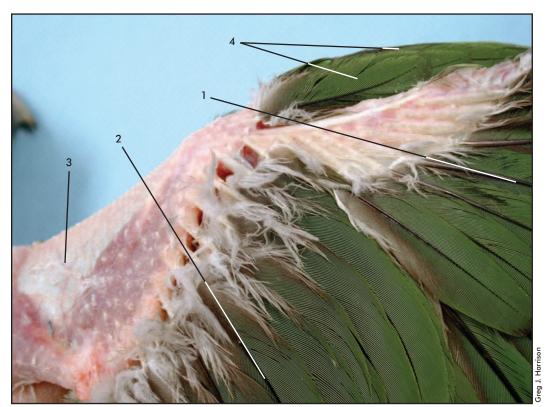

Fig 6.56b | Plumage of the extended right wing. Dorsal view. Upper marginal coverts of the propatagium and the manus removed. 1. Major primary coverts 2. Major secondary coverts 3. Propatagium 4. Alular remiges.

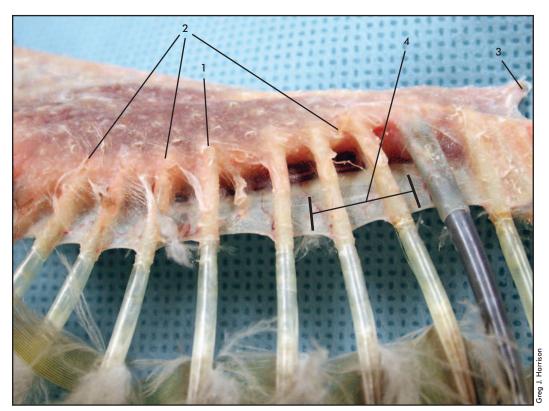

Fig 6.56c | Plumage of the right wing. Dorsal view. Major primary and secondary coverts removed. 1. Secondary remex inserting on dorsal surface of ulna 2. Follicles of insertion for covert feather

3. Alular digit 4. Postpatagium.

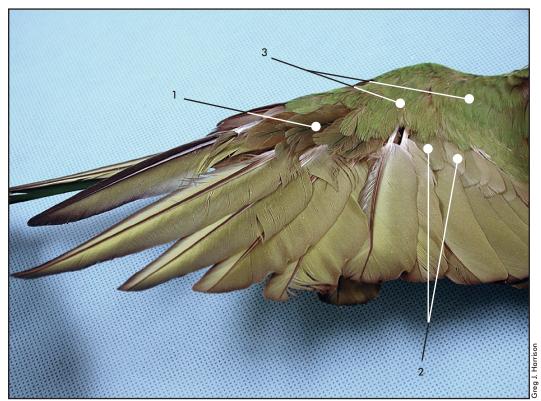

Fig 6.56d | Plumage of right wing. Ventral view. 1. Under wing primary coverts 2. Under wing secondary coverts 3. Under wing marginal coverts of propatagium.

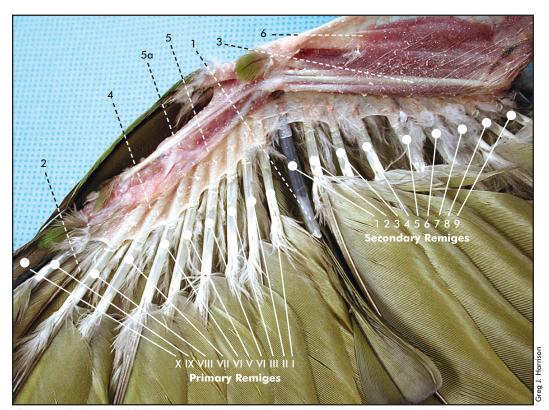

Fig 6.56e | Plumage of right wing. Ventral view. Under wing primary and secondary coverts and the marginal coverts of the propatagium have been removed. 1. Axial secondary pin feather inserting on the dorsal ulna. 2. Upper primary covert 3. Ulna 4. Postpatagium 5. Minor metacarpal III 5a. Major metacarpal II 6. Propatagium. I-X Primary remiges. (I - VI insert on metacarpals; VII the minor digit; VIII-X the major digit) 1-9. Secondary remiges (several additional ones were pulled).

Fig 6.57a | Four-year-old female umbrella cockatoo fed a seed and table food diet. The crest feathers are failing to shed the keratin surrounding the underlying pin feathers. The bald crown area is normal.

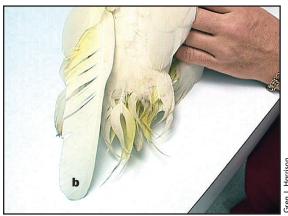

Fig 6.57b | Same bird as in Fig 6.57a demonstrating tattered and broken tail feathers compared to a normal umbrella's wing feather (b).

Fig 6.57c | This close-up demonstrates the difference between stained feathers developed by a bird fed a seed and table food diet compared to a perfect feather being held for comparison.

Fig 6.57d | These wing feathers show a lack of opacity and have a soiled appearance when compared to a perfect feather.

Fig 6.57e | Poor quality rump and tail feathers in a blue and gold macaw fed only seeds and table foods. The feathers lack a sharp vane margin (unzipped appearance). The feather color lacks uniformity and many transverse (stress) lines are present.

Fig 6.57f | Budgerigar on a seed diet with tail feathers unzipped. The lateral rectricies are a dull off-brownish-white compared to those they cover, which are pure normal white but still unzipped.

Fig 6.57g | The parents of this palm cockatoo were fed seeds, vegetables and rancid pine nuts soaked in chlorine bleach to remove molds. This baby was raised on a high protein commercial hand rearing product making up 70% of the diet with the other 30% consisting of 20 g of sunflower seed kernels, 40 g apple and 40 g broccoli. In addition to abnormal plumage there was a deficiency of normal flora in the fecal Gram's stain.

Fig 6.57h | Same bird as in Fig 6.57g 2 months after being removed from described diet. The bird was placed on an organic high fat diet. The head, neck and some wing coverts have molted and regrown in normal texture and color. The bird's timid and nervous attitude was replaced with a jolly playful one. Fecal bacteria were returning to normal.

Fig 6.57i | Same bird as in Fig 6.57g 6 months post-diet change. The color is uniformly normal. The beak has shed much of its retained keratin. The normal red cheek patch took three more months to appear.

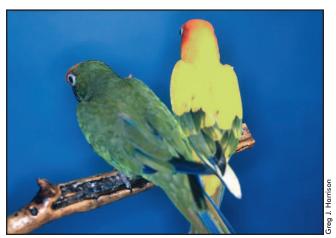

Fig 6.57i | A rectrice with retained sheath and pulp material that is normally shed. This is due to improper nutrient availability to the feathers and a resultant hyperkeratosis. Seed and table food based diets are the major cause (see Chapter 4, Nutritional Considerations).

Fig 6.57k | The two lateral feathers are from a bird with a nutritional disorder. The bird was fed a seed and table food diet. Compare these to the central feather of a bird with normal development on a proper diet. Color, texture, strength, and structure (width of vein) are compared on the feathers' ventral view.

Fig 6.571 | Dorsal views of three normal and three abnormal feathers from the same dietary situation(s) as described in Fig 6.57k.

6.57m | A sun conure and a gold-capped conure fed the same formulated diet. The sun conure developed yellow primary remiges. The addition of red palm oil, high in carotinoids and vitamin E, allowed the development of new blue feathers. The addition of wheat germ for vitamin B did not produce this coloration, nor did other omega 3-6 oils, including fish, flax, borage, evening primrose, corn and sunflower.

Fig 6.57n | Normal lilac-crowned Amazon fed an organic formulated diet.

6.570 | Lilac-crowned Amazon fed a seed and table food diet. The overgrown beak and black pigmentation of the feathers has empirically been associated with advancing liver disorders (see Chapter 4, Nutritional Considerations and Chapter 15, Evaluating and Treating the Liver).

Fig 6.57p | Sulfur-crested cockatoo picks at its neck feathers and is able to pull its crest feathers with feet to chew them. Diet, behavior and integrative therapies (Chapter 10, Integrative Therapies) are often of benefit. A total cure is rare in such feather disorders unless caught at an early stage.

Fig 6.57q | This yellow-naped Amazon with a history of an all seed, nut, table food diet has keratin accumulating on the feet and beak. While fungus (usually Aspergillus) can be cultured from the black feathers, correcting the diet has treated hundreds of birds under the author's (GJH) care with no specific therapy instituted for the fungus. Supportive care is often used, such as milk thistle and lactulose, for regeneration of the liver.

Fig 6.57r | Budgerigar fed a vitamin-enriched seed only diet. While liver disorders in budgerigars are common, this blue budgerigar has black in the blue rump feathers, which is rare. Most budgerigars with liver disorders do not show any indications in their feather color.

Fig 6.571 | A lutino cockatiel with staining of the tail from being dipped in vitamin water, oiled seeds top dressed with vitamins and feces, as the perch was too low. A fungus is growing in the black feather coating but the problem cleared when the sources of contamination of the tail feathers were removed.

Fig 6.57v | A lutino cockatiel four months after therapy for liver disease showing a return to white feathers.

Fig 6.57s | A pied/lutino cockatiel in the later stages of disease. The dark yellow color is associated with a suspected hereditary liver disease. While too late for this bird, a formulated organic diet and liver support in the form of lactulose and milk thistle may be curative if diagnosed early.

Fig 6.57u An 8-year-old lutino pied with advanced gold coloring of the feathers. This bird was fed a seed diet.

Fig 6.57w | Budgerigar with oiled ventral body feathers. Such birds become hypothermic and suffer digestive disorders from preening the oil. Bathing, drying and placing in an incubator at 86° F is minimum therapy.

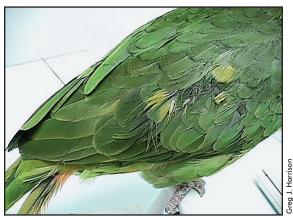

Fig 6.57x | An 27-year-old yellow-naped Amazon with abnormal yellow coverts developed while being fed a seed, table food and nut diet.

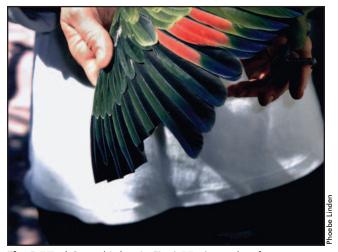

Fig 6.57z | Same bird as in Fig 6.57x 6 months after correcting the diet. The abnormal yellow areas are gone.

Fig 6.58b | Holding the feather by the tip, the feather is slowly flexed tip to shaft. It should rebound to a normal position as in (a).

Fig 6.57y | Same bird as in Fig 6.57x with malcolored yellow primary remiges.

Fig 6.58a | Healthy feathers are flexible with uniform color and structure.

Fig 6.58c | A narrow veined feather that broke (fractured) at the mid-shaft on the flex test. Such easily damaged feathers indicate a nutritional disorder.

Fig 6.59a | Feather lice eggs ("nits") in a canary's tail feathers.

Fig 6.59c | Louse under magnification (100x).

Abnormalities of the feathers and skin should be recorded in a detailed manner. Veterinarians should familiarize themselves with the descriptive terminology used for the external anatomy of a bird. Such precise terminology is essential for later comparisons of progression or resolution of lesions and for describing a case to another veterinarian (see the physical exam form at end of chapter).

The uropygial (or preen) gland is located on the dorsal base of the tail. It is bilobed and is not present in all species (it is absent in many Columbiformes and psittacines, notably *Amazona* spp. and hyacinth macaws but prominent in budgerigars, cockatoos and waterfowl) (Table 6.1).

The uropygial gland should be assessed for evidence of enlargement or inflammation. Impaction, abscessation and neoplasia, all of which may be followed by self-trauma, are potential causes of uropygial gland abnormalities

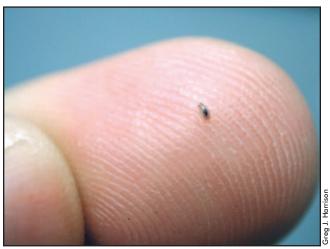

Fig 6.59b | A single louse on a finger. A few drops of alcohol are safe on a healthy bird to obtain lice to show the owners. Debilitated birds should not have alcohol used on them. (20x)

Table 6.1 | Uropygial Gland by Author Observations (GJH)

Uropygial Gland Absent

- Argus pheasant
- Bustards
- Cassowary
- Cormorant
- Citron cockatoo
- Double-headed Amazon
- Yellow-fronted Amazon
- Green-winged macaw
- Grey-cheeked parakeet
- Hyacinth macaw
- Red-cheeked conure
- Emu
- Ostrich
- Tailless domestic fowl
- White carnean and rumples pigeon
- Woodpeckers

Uropygial Gland Present

- African grey
- Blue and gold macaw
- Budgerigar
- Cockatiel
- Eclectus
- · Goffin cockatoo
- Gold-capped conure
- Indian ringneck
- Moluccan cockatoo
- Most Psittacines
- Red-masked conure
- Rose-breasted cockatoo
- Severe macaw
- Sun conure
- Umbrella cockatoo
- Rock dove (wild pigeon)

THE HEAD

The head should be first visualized in profile from a number of different angles, looking for asymmetry. Such asymmetry may arise from exophthalmus, enophthalmos, sinus swelling or depression of the skin over the sinuses. Pupillary size, iris color, lens clarity, feathers surrounding the external acoustic meatus (ear) and relative size of the ears, asymmetry of the cere, size of the nares, appearance of the nasal opercula, rhinothecal or gnathothecal deviations or overgrowth all need to be noted (Figs 6.60a,b) (see physical examination form). Loss of feathers on the head can be due to a variety of conditions. Some cockatiel mutations, especially lutinos, have a bald spot behind the crest. Feather loss in other species can be associated with fungal or bacterial dermatitis, infestation with ectoparasites, allergic dermatitis,

PBFD or excessive grooming by a cage mate. Feather loss around the eyes can indicate facial rubbing associated with conjunctivitis or sinusitis. Matting of the feathers over the crown and nape may indicate the bird has been regurgitating or vomiting.

The conformation of the beak should be assessed (Figs 6.60c-6.61e) for the presence of congenital or acquired abnormalities such as scissor (wry) beak, prognathism and bragnathism. Trauma to the beak or localized sinus infections can result in anatomical abnormalities (eg, longitudinal grooves in the keratin). Excessive keratin flaking of the beak can reflect poor nutrition or simply a lack of opportunity to rub the beak on a suitably abrasive surface (ie, a cement perch). Overgrowth of the beak can occur with PBFD, Knemidocoptes spp., congenital or acquired malalignment of the upper and lower beaks, chronic liver disease or malnutrition. It is rarely the result of a lack of objects to chew on. It is important to note that some species, such as the longbilled corella, Cacatua tenuirostris, naturally have elongated beaks. This should not be mistaken for an overgrown beak.

The cere (Figs 6.62a-c), the fleshy skin at the top of the beak, is not present in all species. In the normal green budgerigar (*Melopsittacus undulatus*) cere color can be used to sex the bird, with cocks having a blue cere and hens a brown cere. However, this will vary with the age of the bird, the color mutation, and the degree of health. Cere hypertrophy — a thickening of the brown cere in the budgerigar hen — may reflect a normal or pathologic hyperestrogenic state.

ORAL EXAM (Figs 6.63a-f)

Examination of the oropharynx can be accomplished by using roll gauze, plastic or metal speculums to open the mouth. In many birds equipment is not needed, as the approach of a light source toward the oral cavity will produce a wide open-mouth reaction and allow visualization. The choana (the slit in the roof of the oropharynx) should be free of excessive mucus or discharge and fringed with well-defined papillae. There should be no abscesses or diphtheritic membranes present. In larger birds, the infundibular cleft can be visualized in the hard palate of the choana. In some cases of severe sinusitis or otitis media, the infundibular cleft will be dilated and contain purulent debris (see Chapter 26, Diagnostic Value of Necropsy).

THE CROP

The crop can be palpated in most birds at the base of the neck, just cranial to the thoracic inlet. It should be carefully and gently palpated to assess if:

- Food is present (ie, Is the bird eating?)
- It feels doughy or fluid-filled, indicating that crop stasis may be present
- Ingluvioliths or other foreign objects are present
- The crop mucosa is thickened
- There is excessive water present
- The crop is overly distended

Care must be taken, especially in debilitated birds, that fluid or ingesta is not propelled retrograde from the crop into the oropharynx and aspirated by the bird.

THE BODY

Palpation of the skin over the trunk occasionally reveals the crackling or air-filled distention caused by subcutaneous emphysema. While this is normal in species such as pelicans, in most species it is the result of trauma or infection in the air sacs that allow the escape of air under the skin.

The abdomen in the normal bird is concave between the end of the sternum and the pubic bones. If this area is convex, then distention is present. The clinician needs to distinguish between internal and external distension of the abdomen. Internal distension of the abdomen can be due to fat, organ enlargement, ascites or the presence of an egg. External distension can be due to subcutaneous fat, neoplasia (especially lipomas), xanthomas or hernias. Radiology may be required to distinguish between internal and external abdominal distension and between different etiologies of both. The use of GI contrast material (barium) may help determine whether herniation is present and what structures may be incorporated into the hernia (Figs 6.64a,b). Abdominal pain or discomfort can occasionally be elicited by careful palpation. In passerines and juvenile psittacines, wetting the ventral abdomen with alcohol may allow visualization of internal organs. The liver should not extend pass the caudal border of the sternum in adult birds. If it does, liver disease should be suspected (eg. atoxoplasmosis in canaries).

If ascites is suspected, careful abdominocentesis may be indicated. After disinfecting the skin over the abdomen, a 23-27 g needle is gently introduced along the midline. If the needle is inserted lateral to midline, ascitic fluid may then communicate with the abdominal air sacs. In larger psittacines, a suitably sized intravenous catheter can be used. Negative pressure with a syringe is applied, and the fluid obtained is processed for cytology, culture and protein analysis. Care must be taken when abdominocentesis is performed that the loss of protein and/or the sudden change in abdominal pressure do not cause serious or fatal results. See Table 6.2 for a cursory list of fluid characteristics and causes. A more complete discussion is available in other texts.

Table 6.2 | Abdominocentesis Abbreviated Results

Nature of Fluid	Diagnostic Possibilities
Yellow-pink, turbid fluid. Cytology shows fat droplets, proteinaceous material, meso-epithelial cells, macrophages, occasional heterophils.	Yolk-related peritonitis
Light colored, clear fluid. Cytology shows few cells of any description.	Ovarian cyst Ascites Various neoplasias
Dark brown fluid. Cytology shows meso- epithelial cells, occasional erythrocytes, heterophils and macrophages.	Renal or hepatic cyst Degenerating ovarian follicles
Thick, gelatinous fluid.	Salpingitis
Fluid of variable color and consistency. Cytology shows macrophages, erythro- cytes and heterophils, possibly bacteria.	Intestinal perforation Serositis

The back should be carefully palpated for evidence of scoliosis, lordosis or kyphosis. As the thoracic and lumbar vertebrae are predominantly fused, flexibility of the spine cannot be assessed as it is in dogs and cats.

The carina of the sternum should be palpated for evidence of distortion, trauma or congenital defects such as splitting. Distortion of the carina, often indicating a history of rickets or other metabolic bone disease, should lead the clinician to recommend radiographic evaluation of the rest of the patient's skeletal system.

The ventral area between the cloaca and the tail should be assessed for splitting of the skin (avulsed pygostyle). This condition may be mistaken for a cloacal prolapse on initial examination, until it is noted that the vent is present cranial to the red, protruding tissue that is actually muscle. This condition is commonly seen in pet psittacines and is associated with a poor diet, obesity and/or excessively clipped wings. Obesity and an excessively severe wing clip can cause the bird to land awkwardly, avulsing the tail from the pygostyle. Malnutrition causes the skin to lose its elasticity. The result is that the skin and underlying muscle in this area split. The initial injury may not be noticed by the owner, but the subsequent bleeding and picking at the affected tissue usually alert the owner to a problem.

THE WINGS (Figs 6.65a-e)

Each wing should be carefully extended and flexed to assess mobility and should be compared to the contralateral wing. The bones and joints should be palpated for swelling or crepitus. Recent trauma may be evident as greenish discoloration of the soft tissue. This is bruising and should not be mistaken for infection or tissue death. If the cause of a wing droop is not detectable after careful palpation, radiology is required to assess the pectoral girdle. The bones of this girdle are covered by strong muscles, and fractures are often not detectable by palpation alone. The patagium should be evaluated for loss of

elasticity, trauma or scarring and for the presence of a tattoo (indicating the bird has been surgically sexed).

THE LEGS AND FEET

Each leg should be carefully palpated to detect abnormalities, such as fractures, healed bony calluses, or angular deformities of the long bones. Soft tissue swelling may be palpable or be suspected by the bird's reaction to palpation. Suspicious areas should be examined for bruising. Each joint should be extended and flexed to assess mobility and range of motion. Joints should also be examined for swelling or the presence of subcutaneous and intra-articular deposition of chalky white uric acid crystals (ie, articular gout). This condition is extremely painful and the bird will often be lame and react violently to digital pressure applied to the affected areas. All aspects of the legs should be compared with the contralateral side for symmetry, length, strength of grip and degree of muscling (Figs 6.66a-d).

The toes should be examined for abnormalities including:

- Missing digits or nails
- Annular constrictions
- Swelling of interphalangeal joints, occasionally with the deposition of uric acid crystals
- Avascular necrosis
- Excessive thinness, especially in neonates
- Abnormal position and conformation of the toes
- · Excessively long or twisted nails

The skin of the foot is an ideal reflection of the rest of the dermis (Figs 6.67a-k). The plantar surface of each foot should be examined and the condition of the metatarsal pads and digital pads noted (Figs 6.68a-g). Abnormalities seen here include: loss of definition of the epidermis (seen as a shiny, reddened surface), swelling, erosions, ulcers and scabs. Pododermatitis (bumblefoot) is common in captive raptors (bumblefoot is never seen in wild, even one-legged birds - S. Hudelson, personal communication, 2004), but can be seen in any bird. A unilateral lameness causes increased weight-bearing on the unaffected leg. This in turn can lead to pressure necrosis, infection and subsequent pododermatitis. Consequently, in cases of a unilateral lameness, the opposite leg should always be closely examined. Bilateral pododermatitis is frequently encountered in older, obese psittacines with a history of poor diet, inadequate exercise and/or unsuitable perches. Note the discussion under Figs 6.67f-i for evaluating nails.

Occasionally, due to the nature of the injury or the disposition of the bird, a full examination may require general anesthesia. If this is the case, radiographs can be taken at the same time, minimizing handling of the conscious (and therefore stressed) patient.

Respiratory/Cardiovascular

AUSCULTATION

When to auscult is the prerogative of the clinician but may be better performed before the bird has been extensively restrained. The heart rate is usually rapid, although that of some pet birds can be surprisingly slow compared to wilder birds. Murmurs, arrhythmias, muffled heart sounds from pericardial effusion, severe tachycardia and bradycardia are occasionally detectable.

Lung and air sac noises can be auscultated, and occasionally friction rubs associated with air sacculitis can be detected. Since the avian lung is basically motionless, the typical mammalian auscultation parameters do not extrapolate well.

CLINICAL PRESENTATIONS

Open-mouthed breathing, abdominal movements and tail bobbing are due to respiratory distress but may also be due to the presence of space-occupying coelemic masses, ascites, anemia, cardiovascular disease, polycythemia, obesity, egg binding and other non-respiratory conditions.

Thyroid disorders in budgerigars can resemble either respiratory or crop/gastric disorders. Dyspnea is not uncommon.

The avian respiratory system is commonly affected by subclinical chronic disease. This is usually due to complications from stress disorders. Malnutrition is the most common cause (see Chapter 4, Nutritional Considerations, Section II Nutritional Disorders). A common presentation is mild nasal discharge that stains the feathers over the nares (Figs 6.69a,b). The discharge usually starts out serous in nature and may progress to mucoid in nature. This tendency seems to be species related. For example, budgerigars tend to be more serous, Amazons are more mucoid. African grey parrots and lovebirds seldom have nasal discharge but build up debris and form rhinoliths (Fig 6.69c). This can lead to atrophic rhinitis.

If the nasal condition is not treated, the lower respiratory tract may be affected (see Fig 6.69d). Sinusitis with resulting ocular discharge may occur (Figs 6.69e,f). If it is confined to sinuses of the head a sinus flush is beneficial for diagnosis. Sinus infections may present with swelling over the infraorbital sinus. There is no simple method to evaluate this diverse air sac system.

Generally, tracheal obstruction can be differentiated from lower or generalized respiratory disease by the sound of the respiration (tracheal noise) and the forward-leaning, neck-extended posture that is assumed by these birds. In cockatiels, tracheal obstruction may be due to seed or seed hull aspiration, especially when the illness is truly acute in nature (as judged by the presentation of a well-fleshed bird). In other cases, cockatiels may demonstrate a loss of voice and/or a squeaky sound produced for several days to weeks prior to the onset of more pronounced dyspnea. These cases are more likely to be due to a granuloma (eg, *Aspergillus* spp.) located at the syrinx, but endoscopy may be necessary to differentiate between these etiologies.

Older and larger birds (African greys, macaws and cockatoos) often suffer from chronic malnutrition with accompanying vitamin A deficiency. This leads to squamous metaplasia and a respiratory environment conducive to *Aspergillus* spp. propagation and granulomas of the trachea and/or syrinx. The eventual prognosis for these birds is guarded at best due to the long standing pathology and the potential for systemic disease.

Upper respiratory disorders tend to show inspiratory dyspnea. Lower respiratory tract disorders tend to show expiratory dyspnea that rarely have audible sound.

The nares, which are normally covered by feathers in many species, are the openings into the rhinal cavity located at the top of the beak. The nares should be symmetrical, open and dry. The normal opercula should not be mistaken for rhinoliths. Blockage of the nares or an area of communicating cul de sacs of the infraorbital sinus may result in a subtle inflation and deflation of the infraorbital sinus. This causes the up and down motion of the skin over the infraorbital sinuses with respiration (see Chapter 4, Nutritional Considerations, Section II Nutritional Disorders).

Neurologic Sensory Assessment

A cursory evaluation of the nervous system should be part of the physical examination. Birds presented for neurologic problems require a thorough neurologic assessment (see Chapter 17, Evaluating and Treating the Nervous System):

- Abnormal conformation or posture
- Paresis or paralysis of any or all limbs
- Fractures of limb bones
- Weakness or inability to grip with one or both feet
- Head tilt, opisthotonos, torticollis
- Altered mentation
- · Decreased visual acuity

Fig 6.60a | Normal beak in a blue and gold macaw.

Fig 6.60c | Close-up view of beak flaking. It may take a year after diet correction for this flaking to abate. This bird is deceased and is demonstrating post-mortem prognathism, a common occurrence, which has no clinical significance after death.

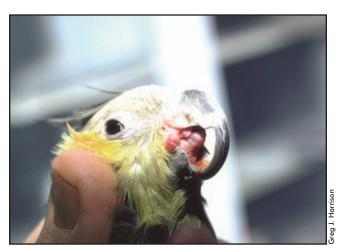

Fig 6.60e | Cockatiel with overgrown maxilla. Such gross overgrowths may be the result of symphyseal fractures of the mandible and the lack of normal wearing of the maxilla. Nutritional deficiencies and trauma may also result in severe maxillary beak overgrowth.

Fig 6.60b | Gray-cheeked conure with amputated maxilla. This will not likely regrow due to the proximal location of the amputation. The excessive pin feathers indicate that a diet or nutrient assimilation evaluation is needed.

Fig 6.60d | Amazon four weeks post-diet change from seeds and table food to a formulated diet. New yellow head and green neck feathers and the flaking beak are positive signs that the bird is responding to the nutritional therapy. Sneezing and itching often accompany this period. A higher fat and protein diet speeds this recovery.

Fig 6.60f | Overgrowth of the rhamphotheca and interlaminal hemorrhage are common in budgerigars fed seed diets with liver disorders. Grinding or trimming is only a temporary solution. Diet change and liver therapy are needed.

Fig 6.60g | Cockatoo with PBFD, necrosis of the maxilla and exposure of the periosteum under the rhamphotheca. Euthanasia is strongly recommended for this presentation of circovirus.

Fig 6.60h | Peafowl chick traumatized by clutch mates.

Fig 6.60i | If not detected early, this traumatized bird will likely be further attacked and killed by its clutch mates.

Fig 6.60i | Scissor beak in a stunted Alexandrine parakeet. Harrison feels this is a form of rickets and myositis from an unhealthy oral epithelium and facial muscle infections, often emanating from nutritional disorders.

Fig 6.61a | A wild rehabilitating starling shows ideal head structures. This bird demonstrates a glass smooth rhamphotheca, impeccable nares and pristine facial plumage.

Fig 6.61b | Another passerine (warbler) shows the model beak and nares, but at this magnification demonstrates retained pin feathers over the crown. This presentation is common in wild birds with toxic substance-related debilitation.

Fig 6.61c | Long beaks are normal for a species like the little (slender-billed) corrella.

Fig 6.61e | Delaminating beak in this Toco toucan is a reflection of a metabolic disorder as it is in other species.

Fig 6.62b | Cere of a yellow-fronted Amazon. These swellings in the cere tissue resemble sebaceous cysts of mammals. They may decrease in size with dietary improvement and weight loss if the bird is obese. They can be expressed but they tend to refill, or they can be surgically removed. Often no treatment is necessary since progression of the cysts is usually halted after a diet correction.

Fig 6.61d | This 20-year-old toucan was fed a toucan pellet for a decade and then an organic low iron nugget for the second half of his life. He had free flight and ate 1/4 of a raw organic papaya daily. Two years after this he died of a pancreatic carcinoma.

Fig 6.62a | The cere of a mature egg-laying budgerigar fed a seed diet. Compare this to the normal cere in Fig 6.4b. The cere is dry, flaky and lacks turgidity. The forehead feathers are predominately immature and have retained sheaths. Malnutrition and other systemic disorders should be on the differential diagnostic list (see Chapter 4, Nutritional Considerations, Section II Nutritional Disorders for the Improper Diet Cascade).

Fig 6.62c | Scaly face (Knemidocoptes spp.) mites cause a powdered look to the beak and a raised honeycomb mass, either on the cere, eyelids, beak, feet or other body locations. Magnification shows pinpoint tunnels in these powdery masses. This is where the mites live. The tunnels are pathogomonic and help differentiate this from other causes of similar lesions. Scrapings may be negative even when mites are present.

Fig 6.63a | The "gape" in a nighthawk. Note the lack of a choanal slit. There are leukoid plaques in the oropharnyx. Candidiasis or trichomoniasis is suspected.

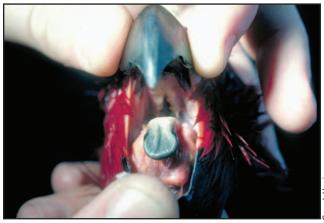

Fig 6.63b | Female eclectus with palatine and sublingual hyperkeratotic salivary "abscess." While usually sterile, the condition is reported to be due to hypovitaminosis A. Therapy with vitamin A and dietary correction containing sufficient vitamin A precursors is appropriate treatment. (Some cases of "foot stomping" in eclectus parrots eating spirulina in the diet improve on dilution of the diet, while others find a correlation with PDD. If not PDD then the "stomping" may decrease over time with no therapy.)

Fig 6.63c | The intermandibular space found in all parrots.

Fig 6.63d | A swelling of the sublingual salivary gland on the left side of the intermandibular space. This lesion is usually a collection of amorphous cellular debris. Surgical resection may be necessary if these sterile abscesses interfere with tongue movement.

Fig 6.63e | An oral speculum in an Amazon with a fungal infection.

Fig 6.63f | The same Amazon as in Fig 6.63e after therapy and dietary correction. While the choanal papillae are reduced in stature and depigmented, they have regrown their pointed characteristic tips.

Fig 6.64a | Anesthetized female budgerigar with an early abdominal hernia. Hernias are correlated with fat accumulating in the hernia area, xanthoma of the hernia sac's skin, ovarian cystic accumulation of estrogen laden fluids and nutritional disorders. Nutritional and hormone therapy should be instituted prior to considering surgery (see Chapter 18, Evaluating and Treating the Reproductive System).

Fig 6.64b | Budgerigar hernia — see Fig 6.64a. A simple skin removal several weeks post-diet change aids in correction. However, if the tissue is xanthomatous, it will not hold sutures

Fig 6.65a | Dermatophytosis in a finch. Skin and feather fungal infections that cause lesions are very rare in birds. Most finches are fed a primarily seed diet. Combine that with crowding, poor air quality, lack of sun and inability to bathe, and the bird's defenses may succumb. Topical and systemic medications are needed, and the primary husbandry issues need to be addressed.

Fig 6.65b | Patagial dermatitis is not uncommon in birds. In birds with nutritional disorders, the skin (and all tissues) lose elasticity. As a result small tears can occur. While viruses have been suspected in lovebirds with similar lesions, none have been reported in most other parrots. Treating for fungal and bacterial infections, topical dressing and splinting to stop motion while changing the diet and husbandry may be curative.

Fig 6.65c | Sternal ulcers are seen in large bodied birds that have had their wing(s) clipped too short and are housed over hard surfaces. The resultant falls cause pressure necrosis (see Chapter 13, Integument and Figs 1.25a-e).

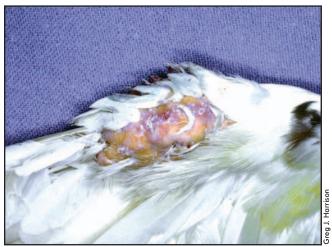

Fig 6.65d | Xanthomas may be seen in birds with nutritional disorders. If treated early, they may respond to dietary correction. Hormonal therapy may be of value in reproductively active hens with xanthoma. In advanced cases, surgical resection is often required.

Fig 6.65e | Lovebird with polyfolliculitis. Multiple feathers form in a single follicle. A necrotizing dermatitis is also present (see Chapter 13, Integument).

Fig 6.66a | Bruising from vascular injury associated with a tibial fracture can be accessed if the feathers are wet or removed.

Fig 6.66b | Peafowl chick hock shows bruising from post-traumatic repair. Subcutaneous blood in birds is often green (biliverdin).

Fig 6.66c | Peafowl chick with a dislocated Achilles tendon. Providing an improved diet, surgical repair and providing the enclosure with a substrate that is not slick may be curative. However, the prognosis is progressively guarded as the species size increases.

Fig 6.66d | A wild passerine in rehabilitation shows the normal nail length, with the nail tapered and needle sharp. This bird has a toxic neuropathy.

Fig 6.67a | Normal Amazon dorsal foot skin patterns.

Fig 6.67c | Acute phase of Amazon foot necrosis can occur in a matter of minutes. The condition usually affects just Amazons (see Chapter 13, Integument).

Fig 6.67b | Dorsal surface of the foot of a free-ranging slender-billed corrella. A severe drought led to water holes drying up and very low natural food sources. The feet are dry but the patterns remain bold. This is believed to be a temporary phenomenon as a result of environmental stress.

Fig 6.67d | Peracute phase of Amazon foot necrosis. The skin will slough over several weeks. No therapy is effective at this stage, but prevention of self trauma and secondary infection may be necessary (see Chapter 13, Integument).

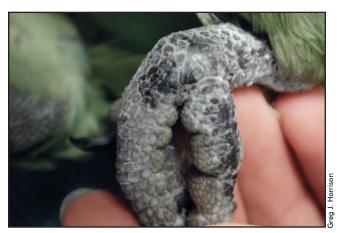

Fig 6.67e | Permanent pigmental scars 3 months after the initial lesions of Amazon foot necrosis.

Fig 6.67f | A free-ranging slender-billed corrella shows the natural nail length and tapering needle points of the nail. Note that while the foot has dry skin, the plantar patterns are still bold. One would expect the dry skin to be replaced in a few weeks if the drought is broken.

èreg J. Ha

Fig 6.67g | This Amazon's nails are thickened and overgrown (see Chapter 4, Nutritional Considerations, Section II Nutritional Disorders).

Fig 6.67i | Finch supplied with synthetic nest material (nylon) has a strangulated digit that needs to be amputated. Natural fibers or nest pads avoid this unnecessary calamity.

Fig 6.67k | Gout tophi is a painful collection of uric acid crystals in the joints and subcutaneous areas of the feet.

Fig 6.67h | Nails of a captive canary on a seed-based diet. In addition to being long and twisted with no tapering, or sharp point, the feet scales are hypertrophic and dry. This could indicate metabolic, parasitic or bacterial disease and/or malnutrition (eg, *Knemidocoptes* spp., staphylococcal or fungal infection).

Fig 6.67i | Papillomatosis of both feet of a finch.

Fig 6.68a | Normal Amazon plantar foot skin patterns.

Fig 6.68b | This warbler shows the normal bold but delicate pattern of a small passerine's plantar foot surface.

Fig 6.68c | Plantar surface of a slender billed corrella. As previously mentioned, the skin is dry but the bold pattern is undisturbed.

Fig 6.68d | Tarsal pad loss of epithelial pattern is common in parrots with nutritional disorders. As they become physically inactive, their tendons seem to weaken and they perch on their hocks. Dietary correction and supportive care, correction of husbandry issues, and alteration of perches may improve this condition.

Fig 6.68e | The degree of development of bald patterns on the plantar surface can be an indication of nutritional disorders. Abrasive perches can exacerbate the problem, but these surfaces do not generally cause plantar excoriation, ulceration or pododermatitis in healthy birds. Large bodied birds may be an exception.

Fig 6.68f | Advanced bumblefoot in a female lutino cockatiel. Anecdotally females develop bumblefoot more often than males in several species (cockatiels, swans, flamingoes and chickens). Nutritional and hormonal disorders need to be addressed.

Fig 6.68g | Mynah bird with bumblefoot and massive tarsal scale proliferation indicative of a metabolic disorder. Nutritional and husbandry issues must be addressed and any secondary infection treated.

Fig 6.69a | A 20-year-old male cockatiel fed a seed based diet shows accumulation of discharge over the left naris and around the eyes, which is typical of sinusitis.

Fig 6.69¢ | Lovebird rhinolith. Nutritional correction and nasal flushes, systemic antibiotics and antifungals are often required. The addition of hyaluronidase to the flush can expedite the breakdown of caseated debris (see Chapter 9, Therapeutic Agents).

Fig 6.69e | Budgerigar with an extensive accumulation of infraorbital sinus serous fluid. This is a very difficult problem to correct. Mycoplasma has been incriminated in some cases.

Fig 6.69b | Budgerigar female with discharge from nares accumulated in frontal feathers. The cere is dry and appears to have fungal growth around the right naris. The bird was old and had obstructive bowel problems that lead to its demise. It was presented for panting.

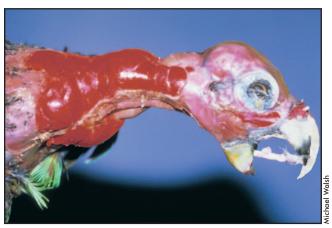

Fig 6.69d | Latex injection mold of the cervicocephalic air sac and the infraorbital sinus (red latex under eye, around naris and the cranial aspect of the beak). A section of a wooden applicator is being used to prop open the oral cavity. (Some latex has run down the rhamphotheca from the nares and more has run into the oral cavity at the commissure of the mouth and on the leading edge of the beak).

 $\textbf{Fig 6.69f} \mid \textbf{Canary with infraorbital sinusitis. Mycoplasma was isolated.}$

Fig 6.70a | The iris of an immature blue and gold macaw.

Fig 6.70b | The iris of a mature blue and gold macaw.

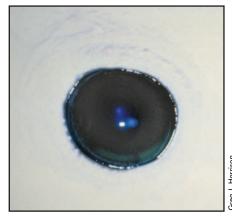

Fig 6.70c | The iris of an immature African grey.

Fig 6.70d | The iris of a mature African grey.

Fig 6.70e | The iris of an immature umbrella cockatoo. This appears the same as one would see in a mature male umbrella cockatoo.

EYES

The eyes should be bright and clear. Ocular discharge and loss or matting of the feathers around the eye indicates either conjunctivitis or sinusitis. Conjunctival hypertrophy is common in chronic conjunctivitis, especially in cockatiels. Mycoplasma has been implicated in this syndrome in cockatiels. Focal light, magnification and fluorescein stain is needed for a detailed ocular examination. Severe or non-responsive ocular disease should be referred to an ophthalmologist familiar with the avian eye when possible.

Determination of the integrity of the globe and neurologic pathways necessary for vision can be difficult. Consultation with or referral to an ophthalmologist familiar with the avian eye may be necessary.

Iris color can indicate sex and/or age. Young birds tend to have a dark iris that lightens as the bird matures. This is true for blue and gold macaws and African grey parrots among others. In many white cockatoos the dark iris lightens to brownish red or even reddish orange in the mature female, while in the male it remains dark.

This is not as prevalent in the umbrella and Moluccan cockatoos as it tends to be in the yellow or citron crested members of this genus. Additionally, it is not a guarantee of gender, and a DNA determination of sex should be made if the gender is questionable (Figs 6.70g-e).

Both nuclear sclerosis and true cataracts occur in birds. In larger psittacines, cataract removal can be accomplished by selected veterinary ophthalmologists. As in dogs and cats, the degree to which the bird is affected by the decreased or lost vision will often dictate whether attempting surgery for cataract removal is warranted.

Various congenital and acquired diseases of the eyelids, cornea, iris, and fundus exist in birds as in other species. Again, there are increasing numbers of veterinary ophthalmologists who are knowledgeable regarding avian ocular anatomy and disease, and a referral may be indicated.

EARS

The ears can be examined by parting the ear coverts with the wooden end of a cotton-tipped applicator or similar

Fig 6.71a | Cloaca everted in a green-wing macaw in order to check for papillomatosis. The small raised area at 9:00 needs to be tested with acetic acid and/or biopsy. Blanching, in response to the application of vinegar, is reportedly diagnostic.

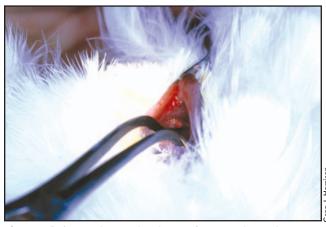

Fig 6.71b | Speculum in the cloaca of an anesthetized umbrella cockatoo. The hypertrophied opening of the ductus deferens onto a prominent papilla is indicative of a male.

appliance. The ears should be open and free of discharge or erythema. Visualization of the tympanic membrane is difficult in most species without the use of an endoscope (see Chapter 24, Diagnostic Value of Endoscopy and Biopsy). Note that the tympanum of birds is normally convex, as opposed to the normal concavity that is found in mammals.

DIGESTIVE AND URINARY SYSTEM

The cloaca can be assessed externally for enlargement and dilation (often indicative of reproductive behavior in a hen), prolapse, ulceration or inflammation around the mucocutaneous junction, and the presence or loss of sphincter tone. Moistened cotton-tipped applicators can be introduced into the cloaca and used to isolate and evert the cloacal mucosa. The mucosa is normally thin, pink and smooth (Figs 6.71a,b). Gently everting the cloaca allows a cursory examination of the mucosa, possibly revealing papillomas in susceptible species. These may be obvious pedunculated protrusions or more subtle thickenings with a cobblestone appearance to the tissues. Suspicious areas can be painted with dilute acetic acid; blanching indicates the presence of a papilloma. A more thorough evaluation of the cloaca requires endoscopy.

REPRODUCTIVE SYSTEM

Refer to the physical examination form, Chapter 4, Nutritional Considerations, Section II Nutritional Disorders and Chapter 18, Evaluating and Treating the Reproductive System for in-depth discussions of reproductive anatomy, physiology and disease (Figs 6.72a,b,g).

Fecal Examination

Birds' droppings are made up of three components: feces, urates and urine (Figs 6.72a2,b2). In a healthy

bird, the fecal portion should be formed and homogenous, with little odor (except for poultry, waterfowl and carnivorous birds). The color should be various shades of brown when the bird is fed a pelleted diet. Seed diets will cause the stool to be a more greenish color. Various fruits, especially those with strong pigments such as cranberries and blueberries, and artificially colored foods including colored pellets, may affect the stool color (Fig 6.72c).

The urates should be a crisp white and slightly moist. If the bile pigments are not adequately resorbed from the GI tract and reused by the liver, the excess of bile pigments, mainly biliverdin, will leach out of the feces and into the urates, causing the urates to develop a greenish tinge. Diet, species, and state of excitation may alter the ratio of urine to feces present in a dropping. Do not confuse true polyuria with "excitement polyuria," the excess urine produced by an excited or nervous bird. See Chapter 16, Evaluating and Treating the Kidneys, for information on polyuria and further diagnostics. Lorikeets, due to their liquid diet, will normally produce large amounts of urine. A close examination of the droppings is a valuable and non-stressful starting point for the clinical examination. Examination of the droppings in the bird's cage that have been collected from the past 24 hours will yield more information than limiting the examination to stress droppings produced enroute to or in the hospital.

Some abnormalities commonly encountered in the avian dropping include:

- Diarrhea unformed fecal portion (Figs 6.72c,f2)
- Undigested food in feces (Fig 6.72f)
- Very bulky droppings maldigestion; malabsorption; reproductively active hens; abdominal growth; pelleted diet (Figs 6.72a2,d,e)
- Melena

Fig 6.72a | Prolapsed uterus in a finch.

Fig 6.72a2 | Normal Amazon dropping seen when the bird consumes an organic formulated diet.

Fig 6.72b | Prolapsed uterus in a budgerigar.

Fig 6.72b2 | Normal passerine dropping.

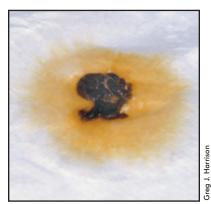

Fig 6.72c | Passerine droppings with artificially colored food items and mild enteritis.

Fig 6.72d | An elderly malnourished female budgie with an obstructive cloacal condition from a uterine tumor. When the obstruction was manipulated, 8 cc of feces were expressed. The owner elected euthanasia.

Fig 6.72e | The normal stress changes observed in the droppings of a parrot that traveled a long distance prior to examination. Droppings at home (bottom); droppings at the clinic (top). The dark color at home (a sign of melena) is not normal.

Fig 6.72f | Passing whole seeds in feces. Various causes of proventriculitis, ventriculitis, and pancreatitis must be considered.

Fig 6.72f2 | A dropping from a parrot with diarrhea is a rare observation.

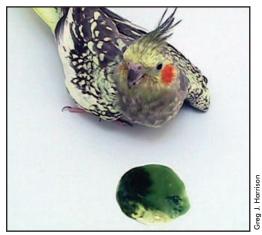

Fig 6.72g | Egg-bound pearly cockatiel passes a loose liquid dropping after having the egg removed. Biliverdinuria reflects the liver stress of the situation.

Fig 6.72h | A parrot's droppings show excess urates with the beginning of biliverdinuria.

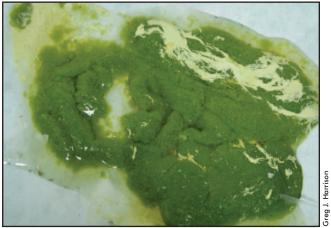

Fig 6.72i | Loose feces from polydipsia in a large parrot.

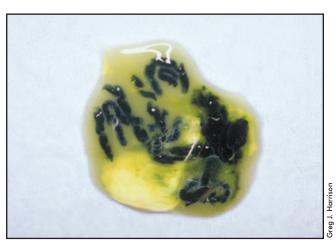

Fig 6.72i | Polyurates with biliverdinuria and feces typical of enteritis.

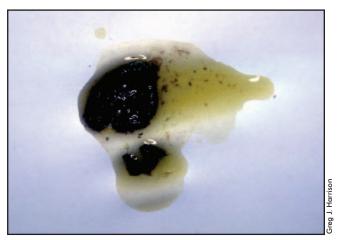

Fig 6.72k | Parrot dropping with PU/PD and biliverdinuria.

Fig 6.72m | A car in Florida (USA), parked under a tree where roosting passerine birds have been eating a local tree's seasonal fruit, demonstrates that they pass large amounts of urates on such a diet.

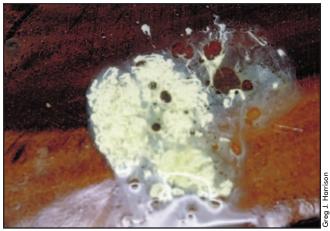

Fig 6.720 | Polyurates with fat. Fat in the urine is rare. Severe kidney damage has occurred, and this bird did not survive.

Fig 6.721 | The droppings from a cockatiel with PU/PD. Hyperglycemia is a common cause of PU/PD, especially in obese adult cockatiels on poor diets.

Fig 6.72n | Polyurates in a bird recently switched to an organic high fat and high protein diet. The pansystemic repair occurring requires massive tissue replacement leading to an increased nitrogen load.

Fig 6.72p | Passing whole blood in the urine after the bird ate the back of an old mirror (mercury). Similar presentations have been seen in lead toxicosis.

- Malodorous droppings bacterial (clostridial or other) or fungal overgrowth
- Aerated droppings also called "popcorn stool" seen most commonly in cockatiels with giardiasis (see Fig 6.16)
- Green urates often indicative of liver disease and biliverdinuria (Figs 6.72e,f,j,k)
- Yellow urates associated with anorexia and liver bilirubin excess (Fig 6.72h)
- Pink/red urates blood, hemoglobin or denatured hemoglobin that may be associated with renal disease.
 Some species, such as Amazons, eclectus and galahs will demonstrate pink to brown urates with lead poisoning
- Orange urates may be due to vitamin B injection in the last few hours or artificial colors in the diet
- Thick, pasty urates dehydration
- Polyuria multiple etiologies, including: heavy metal toxicity, renal disease, sarcocystosis, diabetes mellitus, and pituitary adenoma (Figs 6.72i-l)
- Polyurates (Figs 6.72m-o)
- Anuria etiologies include:
 Obstruction: Fecoliths or uroliths, egg-binding, cloacal prolapse, papillomatosis

 Functional: Renal disease, severe dehydration
- Fresh blood cloacal pathology (Fig 6.72p)

A fresh fecal sample should be collected for a fecal Gram's stain (see Chapter 4, Nutritional Considerations: Section II, Nutritional Disorders), flotation and wet smear evaluation. If there is polyuria, a urine sample can be collected for urinalysis.

Urine evaluation and the urinary system in general is covered in depth in Chapter 16, Evaluating and Treating the Kidneys.

Diagnostic Testing

Veterinarians treating birds (and other exotic species) are faced with challenges often not encountered by their colleagues treating dogs and cats. Many birds are presented to veterinarians only when near-terminally ill, and a rapid tentative diagnosis is often the difference between life and death. Birds are often limited in their range of expression of clinical signs and many clinicians, through no fault of their own, lack the experience to conduct a thorough physical examination. The combination of these factors has led to an increasing tendency in avian medicine to conduct exhaustive diagnostic tests on patients, often with scant attention paid to a complete history and a careful physical examination and with little attempt to refine or focus the diagnostic efforts. The selection of diagnostic tests should be based on a solid

understanding of the species in question and the results of a thorough history taking and physical examination that enable the practitioner to develop an abbreviated list of differential diagnoses.

Before proceeding with diagnostic tests, the clinician should first ask:

- Is the patient sufficiently stable to undergo diagnostic testing, or does it require supportive care prior to sampling?
- Are the physical risks to the patient justified by the likely clinical value of the results?
- Are the test(s) appropriate to the patient (ie, species, age, sex) and its clinical signs?
- Has the test been validated to ensure that the result obtained is likely to be both accurate and meaningful?

If the answer to these questions is 'yes,' then diagnostic testing should proceed.

Diagnostic testing should be done in steps, with the results of each test allowing interpretation and reevaluation of the subsequent diagnostic procedure. Where appropriate, the clinician should endeavor to start with minimally invasive tests (ie, fecal wet smears, fecal flotations and Gram's staining) before moving on to more invasive tests. As each tier is passed, the information gained should allow the clinician to narrow the differentials and perform tests leading to a definitive diagnosis.

The practitioner should be aware that the "normal" values provided by laboratories for serum chemistries, hematology and other parameters are generalizations and are not species-specific. Some of these values are inaccurate and are extrapolated from canine or feline values. The practitioner should be familiar with normals for the species in question, or have a reputable reference text available (see also Appendix).

Clinicians also need to be familiar with the advantages, disadvantages and accuracy of the diagnostic test(s) they employ. There is controversy and healthy debate within avian medicine concerning many of the tests that are currently in use. Examples include:

- Are fecal Gram stains an appropriate diagnostic test to use on healthy patients (see Chapter 4, Nutritional Considerations, Section II Nutritional Disorders)?
- What is the significance of yeast in a Gram's stain?
- How should one interpret cloacal and choanal cultures? Should these cultures be routinely performed?
- Should zinc levels be assessed in patients not showing clinical signs consistent with zinc toxicosis?
- Can a diagnosis of zinc toxicosis be made from a single blood level evaluation?
- Can aspergillosis be diagnosed or ruled out in a patient based solely on serologic tests or culture?

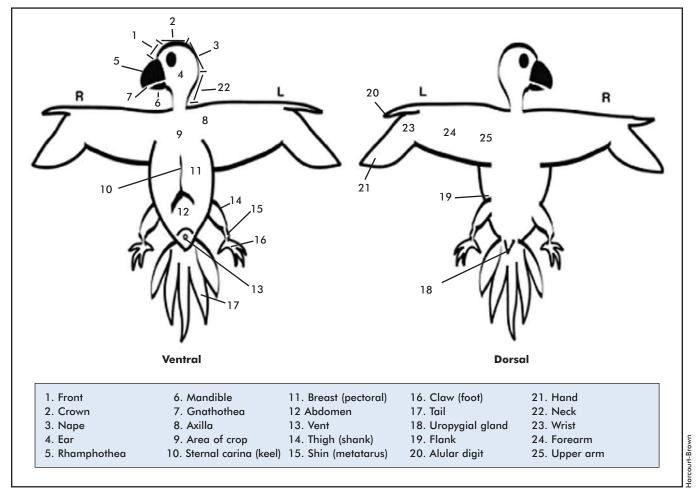

Fig 6.73 | Physical Exam

- How accurate is the differentiation between species of Mycobacterium via serology? What is the true zoonotic potential of Mycobacterium avium? Should birds diag-nosed with this disease be treated?
- Can disease be diagnosed from a positive DNA or PCR test on an asymptomatic patient?
- What is the appropriate interpretation of plasma electrophoresis?
- In what cases are biopsies (eg, renal, hepatic, and pancreatic) warranted? What is the risk/benefit ratio?
- Should crop biopsies be obtained for potential diagnosis of PDD?
- Is skin testing for birds sufficiently advanced to yield clinically useful information?

As we move into the 21st century, it may no longer be sufficient to just have a textbook as a reference on these issues and others. Access to discussion lists on the Internet is an invaluable tool for keeping abreast of current issues. Topics are often discussed on the Internet several years before they appear in even the most recent

textbook. As with all non-peer reviewed information, accuracy may be in question. It is important to trace information to the original source to adequately evaluate the material. Journals, educational CDs, wet labs, annual conferences and regular discussions with colleagues also contribute to the maintenance of current knowledge. Conversely, a solid knowledge of the basics of avian anatomy, physiology and disease generally requires more in-depth study than can be obtained through the above sources. A combination of core textbook study, experience, and Internet and journal-based current information will yield the optimal breadth and scope of knowledge necessary for avian practice.

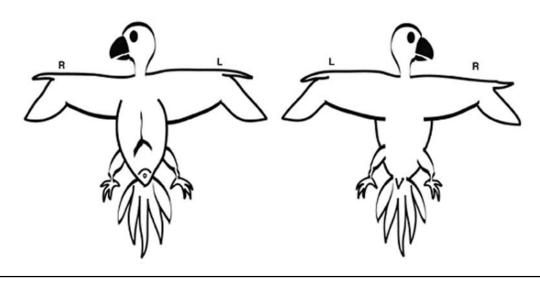

Once again, "you will miss more by not looking than you ever will by not knowing." It is only by a careful evaluation of the patient's history, a thorough physical examination, and the judicious use of appropriate diagnostic tests that the clinician can arrive at the correct diagnosis and implement successful treatment.

Emergency and Critical Care

GREG J. HARRISON, DVM, Dipl ABVP-Avian, Dipl ECAMS; TERESA L. LIGHTFOOT, DVM, Dipl ABVP-Avian; GWEN B. FLINCHUM, BS, MS, DVM

Fig 7.1 | This dyspneic female cockatiel was unresponsive to stimuli and had flexed claws. This bird died shortly after presentation.

Emergency Stabilization

Avian emergencies are typically more challenging than dog and cat emergencies.10 This is because birds tend to hide illness such that by the time they are brought in to be examined they are in an advanced state of debilitation. At this point, handling or other stress may be fatal. Some birds will have such grossly severe clinical signs that handling for examination is contraindicated (see the "Put It Down" List in Chapter 6, Maximizing Information From The Physical Examination). Such clinical signs include pronounced dyspnea (Fig 7.1), prolonged panting or gasping for air, inability to grasp with feet, weakness, inability to bite, closing the eyes during the examination (listlessness), lack of normal response to stimuli and incoordination (see Fig 7.3), marked abdominal swelling, frank blood in feces (Fig 7.2) and fluffed appearance. A lack of fecal material in the droppings (Fig 7.4) and anorexia, especially in smaller birds, can foreshadow impending death, which may be hastened by handling. For this reason, these clinical signs have been referred to as a "put it down" list.21 If such signs are noted during the examination, the bird should be released immediately back into its cage. Very critical patients, especially those that are dyspneic, often will benefit from oxygenation prior to handling. This is especially important with inhalation toxicosis or in cases of tracheal obstruction. The least stressful method of oxygen administration is to place the patient in a chamber connected to an oxygen source to create an environment of 40 to 50% oxygen concentration.31 When possible, the bird should remain in the carrier in which it is presented, and the carrier with the bird inside is placed into an oxygen chamber (Fig 7.5). The bird should remain in the chamber until it is stabilized. Oxygen toxicity from prolonged exposure has been recorded and should be avoided.

Fig 7.2 | Frank blood in the urine portion of the droppings is frequently an indication of renal disease. Mercury and lead toxicoses have been reported etiologies for hematuria. Blood from the cloacal mucosa may be confused with blood in the urine.

Fig 7.4 | Psittacine and passerine birds seldom pass pure urates and urine coated by mucous. Excessive fruit consumption, increased water consumption due to heat, or stress may produce such a dropping in an otherwise healthy bird. Passing such multiple droppings often indicates prolonged anorexia. Also note the yellow-colored bile pigment stain in the urates, indicating hepatic disease. All these indicate a grave prognosis.

Fig 7.3 | In an emergency situation with a dyspneic bird, minimal handling is required to avoid further stress. Placement of the bird into a container and then placing that container into a plastic bag will allow for direct delivery of oxygen.

Fig 7.5 | Covering the cage of a dyspneic bird with a plastic bag and flushing with oxygen can be life saving.

In these critical cases it is best not to handle the patient immediately. Explain to the client possible differentials, prognosis and a plan of action. During this conversation, the client will have time to comprehend the severity of the bird's condition. Also, the owner may add information to the history that will alter the list of differential diagnoses, preliminary treatment or the prognosis. It is essential that the owner have a clear understanding of the prognosis and cost estimation before treatment is begun.

Once the owner has agreed to hospitalize the bird, a plan of action should be formulated. Severely ill birds may die from handling, and one must proceed in a stepwise fashion. One treatment or procedure is performed, and the bird is then placed back in its enclosure and allowed to recover prior to attempting the next diagnostic or therapeutic step.

AIR SAC TUBE PLACEMENT

In some cases, emergency placement of an air sac tube (Fig 7.6a-c) in the caudal thoracic or abdominal air sac is necessary. This should be done in cases of tracheal or syringeal obstruction. Clinical signs of upper respiratory obstruction include gasping for air, often with the neck extended (see Fig 7.1), and/or making "squeaking" sounds with each breath. Air sac tubes are not indicated for respiratory disease below the syrinx or for non-respiratory origins of dyspnea (ascites or organomegaly). For example, primary lung disorders, such as polytetrafluoroethylene (PTFE) toxicity, will not be improved by the placement of an air sac tube, since the air capillaries will still not be able to absorb and exchange oxygen. Abdominal air sac tube placement is contraindicated in lower respiratory conditions such as air sacculitis. These birds may present with whole-body movement during respiration and/or crackling sounds on lung auscultation.

Fig 7.6 | Air sac tube. a) Non-cuffed tube^a and retention disk that is sutured to the skin. b) The tube inserted anterior to the leg (or in the left paralumbar fossa). c) A down feather plucked and used to detect airflow through the tube.

The approach to lacement of an air sac tube is similar to preparation for lateral laparoscopy (see Chapter 24, Diagnostic Value of Endoscopy and Biopsy). The patient is placed in right lateral recumbency with the dorsal leg pulled caudally. The caudal edge of the eighth (last) rib is palpated and the skin over this site is surgically prepped. A small skin incision is made behind the eighth rib. Using mosquito forceps, the muscle wall is bluntly dissected and the body wall is penetrated. A small tube is placed into the hole (Fig 7.6b). To check if the tube is properly seated, place a down feather over the tube opening. The feather should move with each breath (Fig 7.6c). Keep a tight hold on the feather so it is not sucked into the air sac. Care must be taken to avoid iatrogenic organ damage caused by pushing the tube in too far. The diameter of the tube should be the approximate diameter of the patient's trachea. Modified red rubber catheters work well for air sac tubes, as do endotracheal tubes for medium to larger birds. Avian air sac surgical catheters^a are ideal because there is a retention disc attached to the tube that makes suturing the tube to the skin easy and secure (see Tracheal Obstruction later in this chapter).

Supportive Care

SICK-BIRD ENCLOSURES

Sick birds are often hypothermic and should be placed in heated (brooder-type) enclosures^b (Fig 7.7) in a quiet environment (see Chapter 1, Clinical Practice). A temperature of 85° F (29° C) with 70% humidity is desirable for most sick birds. If brooders are not equipped with a humidity source, placing a small dish of water in the enclosure will often supply adequate humidity. A moist towel that is heated and placed on the bottom of a cage or incubator rapidly humidifies the environment, as indicated by the fogging of the acrylic cage front.

Fig 7.7 | A commercial incubator that allows regulation of temperature and humidity. Oxygen can be attached if needed.

FLUID THERAPY

Oral Administration

Oral administration is the ideal method of giving fluids. This method is more commonly used in mildly dehydrated birds or in conjunction with subcutaneous (SC) or intravenous (IV) therapy. Oral rehydration (30 ml/kg PO q 6-8 h) also may be used in larger birds (eg, waterfowl) that are difficult to restrain for parenteral fluid therapy.

Subcutaneous Administration

Subcutaneous fluid therapy is probably the most common method of administration, although administration in very critical patients must be done judiciously. With experience, warm fluids can be given over the dorsum in very depressed birds without restraint or altering of the bird's position within its incubator. Studies have shown that adding hyaluronidase^e to fluids (150 IU/L fluids) greatly facilitates the absorption of these fluids.¹⁷ Subcutaneous fluids are most commonly given in the intrascapular area, the flank, and the area over the pectoral muscles

Fig 7.8a | Materials needed for placement of an intravenous catheter in a bird: isotonic warm fluids, syringe and needle for administering flush, heparin flush (not pictured), plastic-coated intravenous catheterst (24-gauge pictured here), a catheter adapter set (extension), bandage scissors, cotton wool, porous tape, stretch fabric tapez, flexible bandage materialaa (Note: needle and catheter sizes are based on medium to large psittacine patients).

Fig 7.8b | A butterfly catheter (24-gauge) and a much larger 22-gauge, three-quarter-inch catheter for larger birds are possible alternative indwelling catheters for birds.

or the axilla. Maintaining fluids on a heating pad or in an incubator, so they are available at the correct temperature for emergencies, is important. Warm fluids are both an adjuvant treatment for hypothermia and less painful on administration. However, as in mammals, a severely debilitated or dehydrated bird will not absorb SC fluids.

Intravenous Administration

Intravenous administration of fluids is necessary in cases of severe debilitation or severe hypovolemia. However, when dealing with critical cases in avian medicine, difficult decisions must often be made. For example, some patients may die from the stress of being restrained for injection or catheter placement. On the other hand, IV therapy may be imperative in saving a bird's life. Careful consideration must be given to the bird's history and physical condition. Intravenous hetastarch (10-15 ml/kg q 8 h for 1 to 4 treatments) is indicated for hypoproteinemic patients (total solids < 2.0 g/dl).

Intravenous Catheter Placement

Intravenous catheterization facilitates fluid administration; however, catheterization can be challenging due to the small size of bird veins. Avian veins also are more subject to rapid hematoma formation than are mammalian veins. This is especially true with the basilic (wing) vein. Catheter placement may be more easily accomplished with the bird anesthetized, although the risk of anesthesia must be considered. Furthermore, catheter maintenance may be difficult, especially if the bird is prone to chew at the site. Elizabethan collars can be placed to prevent this, but often result in further stress to the patient.

Intravenous plastic-coated catheters (IVC) (Figs 7.8a,b) and the related plastic tubing and various rubber adapters — all derived from human pediatric medicine — have made catheter placement in small birds possible (Figs 7.9a-g). Anesthesia may be required for catheter placement and proper securing of the catheter and line. Once placed, the security of the adhesive materials incorporated into these devices, combined with the severe debilitation of the patients in which these catheters are utilized, makes additional restraint or mechanical barriers usually unnecessary.

With the advent of the use of hyaluronidase in subcutaneous fluids the IVC is seldom required. The multidose IV fluid technique also works on most cases in which subcutaneous fluids with hyaluronidase are inadequate. The disadvantage to bolus IV fluids is that they cause hypervolemia with subsequent polyuria; therefore, less fluid is retained than with a constant rate infusion IV drip. This drawback is minimized by the use of a syringe pump that will deliver as little as 1 cc of fluids over periods of up to 1 hour.

Other Fluid Therapy Methods

An alternative to IV catheterization is intraosseous (IO) catheterization of the distal ulna or proximal tibia. This method is very useful during the first 24 to 48 hours of initial hydration and shock therapy. It also is used to maintain hydration and IV access during prolonged procedures, such as complicated orthopedic repairs. In the latter case, the IO catheter can be placed after the patient is anesthetized, avoiding the pain and stress related to its placement. Insertion of IO catheters tends to be painful and often necessitates anesthesia for placement.

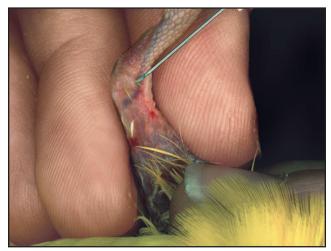

Fig 7.9a | Placing an indwelling catheter in the medial metatarsal vein on a lovebird's leg. The vein is occluded at the proximal tibial-tarsus.

Fig 7.9¢ | The catheter is advanced to the hub. The hub is taped with a 3- to 4-mm-wide and a 4- to 5-cm-long piece of waterproof adhesive^{bb} tape in the fashion shown.

Fig 7.9b | A 24-gauge catheter needle has entered the metatarsal vein. Note the entry site is just the distance of the catheter hub length proximal to the hock. This creates maximum catheter stability when the taping snugs the hub into the depression proximal to the tibioltarsus' distal condyles.

Fig 7.9d | A small tuft of cotton wool is wrapped around the leg.

Fig 7.9e | An extension with an injection port has been attached to the catheter and it is folded along the skin and covered with cotton wool.

Fig 7.9f | A layer of cohesive flexible bandage^{aa} is wrapped over the catheter, extension and injection port.

Fig 7.9g | The site is wrapped with stretch fabric tape. Fluids can now be administered by bolus as often as desired, or an IV pump can be attached and a continuous drip administered.

Fig 7.10 | An intraosseous needle and the insertion handle.

This may be too stressful for critically ill birds. An IO needle with a handle^{a1} (Fig 7.10) is available and makes catheter placement easier and more precise.

Rectal fluids also may be effective. Posturetal urine can be modified in the rectum after retrograde movement from the coprodeum and subsequently be reabsorbed. In an experimental study, four out of six pigeons were rectally infused with a hypotonic solution, which successfully maintained hydration.23

PROTECTIVE DEVICES

Various traumas, postsurgical patients and cases of selfmutilation may require the placement of a mechanical barrier to prevent self-trauma. Some birds require little physical distraction (Fig 7.11a). Historically, circles of exposed radiographic film were designed to encircle the neck, forming a type of Elizabethan (E.) collar. Various types of padding used in conjunction with these collars creates a safe and effective barrier to self-mutilation.

Such devices have several drawbacks, however: they are time-consuming to custom make; one must ensure that the collar itself does not abrade or otherwise injure the bird; if the padding is not properly applied, the film's sharp edge may cause abrasions or lacerations circumscribing the cervical area; additionally, the collar must be designed such that the bird does not destroy it. Radiographic film is not very durable and is challenging to apply (Fig 7.11b).

Plastic disks are commercially available, but many are heavy and cumbersome (Fig 7.11c); birds may stumble and fall, have difficulty perching and/or accessing food and water (Fig 7.11d). These collars may become entrapped in the cage or on cage items. Almost all birds will go through a period of agitation in response to application of these "collars." Flapping in a circular, spastic manner for a prolonged period is not uncommon. Additional padding can be applied to avoid damage to the propatagium during these violent episodes;

however, this again adds additional weight to the collars and makes them more cumbersome.

Regardless of the material used, E. collars can be applied facing one of two directions. Applying them with the wide portion forward (cranial) allows for better balance and does not interfere with wing movement; however, it is more likely to impede eating and drinking, and the visual presence of the collar surrounding the bird's head often frightens the bird. If the collar is applied facing backward (with the wide end caudal), the bird can more readily access food and water and can see its surroundings without visual impairment; however, with the collar in this position, the wings cannot be extended for balance. In some cases, the collar must be left long enough to prevent the bird's access to its legs and feet. In these cases, the length of the collar is often significant and the bird will tend to trip on it as it attempts to ambulate.

Plastic disks that provide a neck ring of harder plastic or metal are available. These neck rings may break and some of these devices have a screw-type clamshell neck portion that is very difficult to apply without anesthesia.

Various custom-made, padded cervical collars have been utilized (Fig 7.11e). These are measured from the thoracic inlet — with the neck fully extended —to the mandible. A compressible material consisting of a rubber or plastic foam, such as a swimming pool float or the insulation used to encase refrigeration piping and covered with an elastic tape, has worked well in this author's (GJH) experience. Disposable baby diapers or similar human pads used to absorb urine and feces also can be shaped into lightweight, flexible neck collars (Figs 7.11f,g).

An additional device is a plastic "lego"-like, locking, ballooned out collar (Fig 7.11h). Care must be taken to avoid entrapping the bird's feathers in the device, preventing it from locking. If the bird falls or hits this device it may snap open and fall off.

Regardless of the protective device selected, a primary concern is that the application of the collar does not cause injury to the patient. Various combinations or devices and alternating applications may be necessary.

Removing the collar for a period of time each day so the bird may preen will decrease the stress to some birds during prolonged use of a collar.

The use of collars for feather-destructive behavior is seldom warranted, although their use in cases of self-mutilation can be life saving. This is where the clinical distinction between feather destruction and self-mutilation becomes critical.

Fig 7.11a | This cockatiel needed only the minor distraction of the decorative portion of a child's sock to discourage picking.

Fig 7.11b | A severe case of Amazon foot necrosis that occurred prior to the advent of newer treatment techniques. Such cases faced months of collaring. This collar was reinforced with a heavy-duty fabric tape used in the construction industry. Note that the bird managed to pull in the disk's edge and remove part of the tape. This collar also produced a weight burden for the bird.

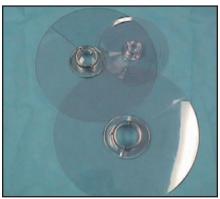

Fig 7.11c | Plastic circular disks use a plastic clamshell shape to envelop the neck. The sleeve comes in two parts and is joined by metal screws. Variations of this collar have a padded, rubber-like cervical edge and metal snaps.

Fig 7.11d | An Amazon is collared to prevent feather-destructive behavior. The bird's nutritional disorders, hormonal imbalances and behavior problems were not being addressed. The use of a collar without addressing the underlying problem is inhumane.

Fig 7.11e | A cervical brace-type protection device made from a padded material. While still requiring a period of adjustment, this variation seems superior to the extensive Elizabethan collar for comfort and rapid return to normal function.

Fig 7.11f | A section of black refrigeration pipe insulation that can be cut into various lengths to fit the cervical area and prevent mutilation. Elastic fiber tape makes a durable coating.

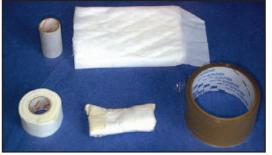

Fig 7.11g | Human diaper pads can be used as padding material that is taped to offer durability and attached for a custom-made cervical brace protective device.

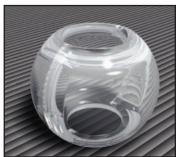

Fig 7.11h | A plastic clamshell protective device with a soft bubble section shaped to prevent the bird from reaching its body. The manufacturer reports faster adaption and a higher rate of comfort.

Birds that have E. collars applied should be kept in the hospital until they have acclimated to their presence. Some birds have an initial reaction of constant flipping and flailing. These birds should be placed in a padded but otherwise empty incubator and observed. The use of a medication such as medazolam prior to the application of an E. collar may aid in its acceptance. Acclimation here is defined as being able to move around a normal cage and access food and water. The collar may require modification or reinforcement, either to facilitate ambulation or to provide a more extensive barrier to self-mutilation. Chewing at the collar may persist to some degree throughout the period it is worn.

Applying a protective barrier to a bird without consideration for and treatment of the underlying etiology is both poor medicine and potentially cruel. If a less cumbersome device can be used, it should be applied.

ANTIBIOTIC THERAPY

The unnecessary use of antibiotics in veterinary medicine is a current concern. When practical, diagnostic testing should be done prior to the initiation of therapy. Minimally, confirmation of the need for antimicrobial therapy should be determined by response to treatment. Complete blood counts should be performed if collecting blood will not endanger the patient. Culture and sensitivity tests can identify infective organisms and the appropriate medication choices; however, it may take several days to get culture results, which is unacceptable for emergency therapy. Fecal, throat or crop Gram's stains can be done quickly, are relatively non-invasive and can be useful in making therapy decisions. Although indiscriminate use of antibiotics is discouraged, prophylactic use may be indicated on the basis of clinical signs and history for birds that cannot undergo further testing.

Antibiotics are commonly given intramuscularly (IM). Although this route is quick and effective, recently there has been concern about muscle necrosis and pain associated with IM administration. It has been suggested that medications be given SC, especially in smaller birds with less muscle mass. Controlled studies are needed to see if absorption from this location will provide adequate blood levels of antimicrobials.

Many critically ill or septicemic birds require IV injections. This requires repeated venipunctures or catheter placement. Disadvantages of IV injections include the possibility of extravasation, hematoma formation and stress to the patient.

ANTIFUNGAL THERAPY

Ideally, antifungal therapy is based on culture and sensitivity testing. This is almost never done in practice due to

the extended period of time involved, the lack of laboratory support for such studies and the lack of a wide-range of therapeutic choices. Gram's stain results, such as budding yeast or fungal hyphae, or confirmation of aspergillosis or other fungal infection through cytology or histopathology will help confirm a diagnosis. Antifungal medications also may be indicated during antibiotic therapy to decrease the risk of secondary yeast infections, especially in immunosuppressed birds. Birds with a history of malnutrition and chronic respiratory disease may benefit from prophylactic use of antifungal medications until a diagnosis can be made. Aspergillosis secondary to chronic vitamin A deficiency and subsequent squamous metaplasia may be an underlying problem in these birds. Among pet birds, Amazons (Amazona spp.), 1,14 African grey parrots (Psittacus erithacus)^{1,25} and macaws (Ara spp.) appear to be especially susceptible to aspergillosis. Antifungal medications exhibit diversity in their mechanisms of action, toxicities and cost. An understanding of these properties will enable intelligent decisions as to which drug is appropriate for a particular situation.

MISCELLANEOUS MEDICATIONS

Corticosteroids

Corticosteroids have been widely debated due to the potential complications arising from their use. ²⁶ These side effects include immunosuppression, adrenal suppression, delayed wound healing and gastrointestinal ulceration. Most of these side effects are seen following a prolonged course of administration of corticosteroids, although reports of potential glucocorticoid-induced adrenal suppression after topical use have been cited.

However, single doses of corticosteroids have been reported to improve the prognoses in cases of shock, trauma and toxicity³¹ without the occurrence of clinically observable adverse side effects. The use of corticosteroids is not recommended in birds that have had a history of immunosuppression or fungal disease. Dexamethasone sodium phosphate (2 mg/kg IM or IV once) is the preferred steroidal anti-inflammatory for birds.⁴ Prednisolone sodium succinate (0.5-1.0 mg/kg IM or IV once) has been reported to be most effective in cases of neurologic emergencies (see Stress in Chapter 19, Endocrine Considerations).

Glucose Therapy

Hypoglycemia may be present in cases of malnutrition or starvation, sepsis or hepatic dysfunction. This is seen most often in passerines, but seldom in psittacines and occasionally in raptors. Blood glucose levels can be determined on a laboratory panel, and levels will fall to below half of the normal for the species in hypoglycemic patients. Severe cases must be treated immediately, as

symptoms may include seizures, weakness and depression. Treatment includes IV administration of 25% dextrose (1-2 ml/kg slowly to effect), although dextrose alone should not be used in dehydrated patients. Oral solutions such as honey or Karo® syrup also can be used in birds that are not prone to aspiration. The underlying cause, if hypoglycemia, must be subsequently determined and corrected.

o,p'-DDD

Mitotane, or o,p'-DDD, is an adrenal-blocking drug that has been shown to inhibit stress-induced hypersecretions of corticosteroid, thus bolstering immunocompetency during stressful situations.¹³ Adrenal blockers also have been shown to arrest tumor growth and inhibit stress-induced tumor metastasis.¹¹ o,p'-DDD is used in cases of suspected immunosuppression and for neoplastic conditions. Its use should be avoided in cases of suspected pesticide toxicity.

ORAL NUTRITIONAL SUPPLEMENTS

Below are listed some of the oral nutritional supplements that can be gavage-fed to debilitated birds. Various hand-feeding formulas are on the market and, as a whole, are far superior to the homemade formulas used decades ago that contained monkey biscuits, peanut butter and ground seeds. Commercially available hand-feeding formulas for baby birds are often utilized in the treatment of sick and debilitated adult birds. The quantity that can be fed at one time to a sick bird is greatly reduced from that of baby birds. On the average, a baby parrot can accommodate 10% of its body weight per feeding due to the elasticity of the crop and its rapid emptying. Adult birds have a greatly decreased crop capacity, averaging 3% of their body weight. Additionally, sick birds are less tolerant of food in the crop and care must be taken to avoid regurgitation and/or aspiration.

A sick or debilitated bird should always have its hydration corrected prior to attempting to initiate oral gavage-feeding.

Some formulas that are used and the indications for these are summarized below. None of these formulas is indicated in the presence of ileus. Many ill birds are captive-raised and were hand-fed, and these patients may respond to hand-feeding techniques (Fig 7.12). This facilitates both feeding and medication administration.

Carbohydrate Supplement

A simple carbohydrate powder (fructose and malt dextran) can be mixed with water, Tyrode's solution or Normosol-R to make a non-viscous tube-feeding solution. This is useful for birds to resolve crop stasis because the

Fig 7.12 | Hand-feeding a sick bird using a warmed hand-feeding product may be attempted prior to tube-feeding. Hand-feeding will be more time-consuming but less stressful for the patient if accepted.

thin consistency of the carbohydrate supplement mixture is more digestible than regular hand-feeding formulas. It also is useful for hypoglycemic patients or those with primary liver disease. Another similar product^k is recommended for patients with primary hypoglycemia or for birds needing additional calories provided as highly digestible carbohydrates.

Following rehydration in sick birds, the liver needs adequate carbohydrates to carry out its functions, so carbohydrates are next in line as nutriceuticals for ill birds. Carbohydrates are generally followed by a more complex oral nutritional formula within 24 to 48 hours.

Carbohydrate Metabolic Detoxifierh

Based on a rice protein concentrate, this product works as a metabolic detoxifier for the liver while also providing calories. This is useful in cases of chronic liver disease and when severe biliverdinuria is present. It is used for several days following the initial use of the carbohydrate-only formula. This is usually followed by the use of the hand-feeding formula or a sick-bird support formula.

Sick-bird Support Formulas

Medical and surgical patients are often undergoing pansystemic debilitation. A product with simple proteins (isolated soy protein) and simple familiar fats (hi-oleic sunflower oil) is added to the carbohydrate supplementation listed above to further meet the bird's nutritional requirements. See the discussion on carbohydrates in Chapter 4, Nutritional Considerations for the raffinose values of soy.

Many surgical and medical patients have been fed a seed diet and need the additional nutritional support gained from the administration of a balanced formula.

The method of administration of the supplemental formula will depend on both the patient's condition and the experience of the person administering the food.

- 1. Hand-feeding can be an ideal way to supplement birds that revert to baby begging and feeding behavior when ill. However, the administration of a sufficient quantity of supplement at each feeding requires that the patient be strong enough to demonstrate an adequate feeding response, and that the person feeding be experienced enough to avoid causing aspiration of the material.
- 2. Gavage-feeding also requires experience. When gavage-feeding is performed, the experienced person will be capable of avoiding the following inherent dangers:
 - a) Mechanical damage to the oropharynx with the metal crop feeder
 - b) Damage to the beak with inappropriate use of oral speculums
 - c) Accidental tracheal gavage
 - d) Reflux of the formula from the crop into the oral cavity

(See Chapter 1, Clinical Practice).

Precautions: Feeding sick birds should not be attempted by inexperienced persons. Do not attempt to hand-feed birds that are not aggressively feeding. Do not use formulas that are too cold or too liquid. Feedings must be accomplished promptly to avoid appetite loss. Failure to heed these cautions could result in aspiration and death.

Hand-feeding Formula^d (Fig 7.13)

Although originally formulated for hand-feeding juvenile birds, these formulas have been ideal for nutritional support of malnourished birds or as a tube-feeding formula for sick birds. The average dose for psittacines is 30-60 ml/kg per day, divided and dosed q 6-8 h for an adult bird, in addition to parenteral fluid administration, assuming normal gastrointestinal motility.

TOTAL PARENTERAL NUTRITION (TPN)

Total parenteral alimentation is the IV administration of all essential nutrients. Indications for use include gastro-intestinal stasis, severe head trauma that precludes oral alimentation, and malabsorption or maldigestion.³¹ Although parenteral alimentation has been described, ^{9,30} it is not routinely utilized in avian medicine. There can be difficulties in placing and maintaining a catheter, and sepsis and bacteremia can occur if the catheter becomes contaminated. The constant monitoring of the electrolyte and acid/base blood values for adjustments to this formula is blood volume-prohibitive in pet birds.

Total parenteral nutrition given intraosseously (TPN/IO) was reported in 1995 and was tried experimentally on pigeons. Hyperglycemia and glucosuria were encoun-

Fig 7.13 | A formulated diet designed for hand-reared psittacines. The psyllium in this product^d cleans the digestive system, improves hydration and helps restore electrolytes while reducing toxins and cholesterol. This product delivers 1.5 Kcal/ml when reconstituted.

tered and resulted in the death of one bird. Another bird had complications at the site of administration. No further reports are currently available. Financial constraints may be an additional reason that parenteral nutrition is not being administered to avian patients. A recent e-mail (TPN January 9, 2003 xoticvet@shaw.ca on exoticdvm@yahoogroups.com) stated that the cost of having a pharmacist compound a TPN formula was \$100 Canadian for 300 ml, and the shelf life was very short (several days).

FREQUENTLY SEEN EMERGENCIES

Liver Failure/Malnutrition

Malnutrition is a major cause of liver disease in birds eating seed-only diets. This is due to the high fat and low nutrient content of seeds. As with many diseases in birds, no clinical signs may be apparent until the patient is in an advanced stage of decompensation. Clinical signs may include lethargy, inappetence, diarrhea with loose green feces and green or gold urates (Fig 7.14) (see Chapter 4, Nutritional Considerations, Section II). There may be no abnormalities on the serum chemistries of these patients, although elevations in either the hepatic enzymes or bile acids may be present. ¹⁶ Hepatic disease with malnutrition as the underlying cause may present commonly as hepatic lipidosis, fibrosis and cirrhosis.

Routine dorsoventral and lateral radiographs can be helpful in identifying hepatomegaly or decreased liver size. Bag radiographs (see Figs 1.17a,b,c, 1.18a,b) are non-invasive and can be done by placing the bird in a paper bag for radiography. This technique is useful for

Fig 7.14 | Bilirubin in the urates, an indication of hepatopathy.

Fig 7.15 | Milk thistle^m with a vegetable glycerin base is used as an oral supplement to aid hepatic regeneration.

screening for the presence of heavy metal densities, but not reliable for determination of hepatic size (see Chapter 1, Clinical Practice for information on bag radiographs).

Response to treatment for malnutrition-induced hepatic disease depends on the duration of the disease and the extent of organ dysfunction. Treatment includes parenteral fluid administration, treatment of any concurrent infection and gavage-feeding with an appropriate formula. In one author's (GJH) practice, this is more specifically defined as the administration of subcutaneous fluids, and tube-feeding with sick-bird support formulas^d.¹ If recovery is possible, a response to treatment should occur within 24 to 48 hours. In the presence of a leucocytosis, with or without hepatic enzyme or bile acid elevations, antimicrobials are routinely used by one author (TLL). These are empirically based on the CBC differential and fecal Gram's stain and may often include both antibiotic and antifungal agents.

Milk thistle (silymarin^{m,12,34,37}) has been shown to improve liver function and enhance regeneration of damaged liver cells (Fig 7.15).

Various other medications may be added to aid in hepatic function (see Chapter 15, Evaluating and Treating the Liver).

A diet change from seeds to a formulated diet is imperative in long-term successful treatment.

Egg Binding

Egg binding is common in lovebirds, budgerigars, cockatiels, eclectus parrots and older Amazon parrots (10 years or older) that are usually fed seed-based diets. Clinical signs include swollen abdomen, fluffed appearance and lethargy. Often, birds will act as if they are trying to defecate but cannot; therefore, the client concern

may be "constipation." A retained egg may be palpated in the abdomen, although care should be taken not to confuse a caudally displaced ventriculus for an egg during palpation of the sterno-pubic area. Radiographs are recommended to help identify soft-shelled eggs or double eggs, as well as secondary problems such as an enlarged liver shadow or coelomic fluid accumulation.

Treatment includes parenteral calcium supplementation (if the shell is soft), SC fluids and supplemental heat (see Chapter 5, Calcium Metabolism). Oxytocin (5 IU/kg IV or SC once) has been recommended to help in egg expulsion. It has been reported that oxytocin can have adverse side effects and should be used only if the uterovaginal sphincter is well dilated and the uterus is free of adhesions. However, since oxytocin is not the primary hormone of uterine contraction in birds, it is only partially effective, and the effect of exogenous administration is diminished. Both prostaglandin F-2 alpha and prostaglandin E are reported to be effective in cases of egg binding. Prostaglandin F-2 alpha is more readily available, although it also carries the concern of oviduct rupture if the utero-vaginal sphincter is not dilated. Prostaglandin E is used in human obstetrics. Egg extraction via the cloaca is the least invasive method and can be utilized in most cases (Fig 7.16). When dealing with soft-shelled eggs, eggs adhering to the oviduct or uterus, or cranially located eggshell fragments, laparotomy may be necessary. Collapsing the egg with a syringe and needle (implosion) may facilitate removal. When the egg cannot be visualized via the cloaca, this may be due to complications such as an impacted uterus or mummified egg. During egg extraction all shell material must be removed. If left in the uterus, shell fragments tend to migrate proximally, making retrieval very difficult. The use of delivery forceps, feeding needle, syringe, and cotton-tipped swab facilitates egg or egg fragment removal (Figs 7.17a-c). The collapsed egg can occasionally be

Fig 7.16 | An egg-bound bird with the eggshell adhered to the uterus. This is typical in birds with nutritional disorders.

saline, an ophthalmic speculum, metal feeding needles for flushing, and a curved-tip forceps for dilating the uterus and grasping the shell of a collapsed egg.

Fig 7.17b | Anesthetized female positioned over a towel to aid in proper cloacal inspection. The tail is perpendicular to the spine.

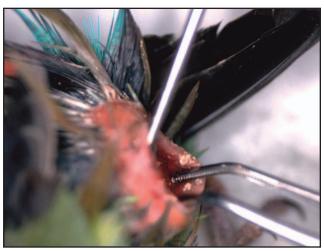

Fig 7.17c | A lateral view of the forceps dilating the cloaca and the feeding needle in place to puncture the egg, aspirate the contents or flush out shell fragments.

Fig 7.18 | Expressing a collapsed egg after it has been aspirated transabdominally.

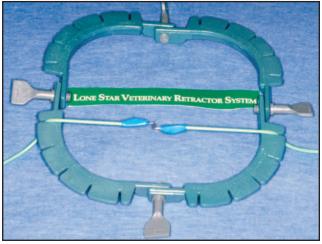

Fig 7.19 | A retractorⁿ makes cloacal examination much easier.

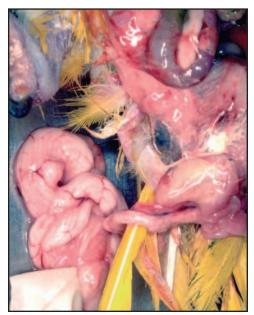

Fig 7.20 | A ruptured uterus allowed the egg to become retro-coelomic, causing death in this cockatoo.

removed intact (Fig 7.18). Use of a retractorⁿ (Fig 7.19) makes visualization much easier. (See Chapter 35, Surgical Resolution of Soft Tissue Disorders for more on retractor use. See Chapter 18, Evaluating and Treating the Reproductive System for forceps and procedures). Occasionally the uterus will rupture and the egg will be free within the coelomic cavity (Fig 7.20).

The rigid, semi-flexible (Fig 7.21) or flexible endoscope for egg delivery is useful. Warm saline/air flushing and insufflation with the endoscope can make visualization and subsequent egg particle removal much less stressful than blind forceps delivery. This is especially true for eggs that have migrated proximally and for retrieval of eggshell fragments. Once the egg has been removed and the bird is stabilized, a series of leuprolide acetate (500- $1000 \,\mu\text{g/kg}$ IM q 2 weeks, 3 times)^{3,38} or chorionic gonadotropin (HCG) (500 IU/kg IM on days 1, 3, 7, 14 and 21);22 injections have been recommended. One author (GJH) has found diet change from seeds to a formulated diet mandatory for full recovery and prevention of recurrence. Dexamethasone has empirically improved the response to HCG injections (see Chapter 18, Evaluating and Treating the Reproductive System for an excellent review).

Tracheal Obstruction

Tracheal obstruction is frequently seen in cockatiels subsequent to seed inhalation. In larger species of psittacines, tracheal obstruction is often due to the presence of tracheal granulomas or aspergillomas that impinge on the tracheal lumen. The history of these birds

Fig 7.21 | A semi-flexible endoscope for examining the salpingouterine area in an egg-bound bird.

often includes primarily a seed diet, with subsequent vitamin A deficiency. Clinical signs include open-mouthed breathing with a high-pitched squeaking noise emitted each time the bird breathes. The bird will often have a forward-leaning posture as it attempts to increase air intake (see Fig 7.1). Flexible and rigid endoscopes can be used for oral approaches to the larynx and trachea. A 1.2 mm x 20 cm semi-flexible endoscope^o (see Fig 7.21) is a valuable tool for visualizing and identifying the tracheal obstructions in birds under 100 g. Nebulization can be used to soften obstructive material. A needle can be placed through the trachea to prevent distal migration of the material. The bird is then held upside down and suction is applied until the obstruction is resolved. With cockatiels, a tom cat catheter can be utilized to provide a tube of appropriate diameter for aspiration of the material. A surgical approach to the thoracic inlet has been described and may be used to remove foreign material, but the surgical risk is significant.2 A final option is to push the foreign body into one main-stem bronchus and into the lung, and follow up with aggressive antibiotic and antifungal therapy. Air sac tube placement (discussed earlier in this chapter) will likely be necessary for any attempted treatment. Without an air sac tube, the bird's respiration may be severely compromised by the presence of equipment in the trachea (see Chapter 24, Diagnostic Value of Endoscopy and Biopsy and the previous section of this chapter regarding air sac tube placement).

Vomiting and Regurgitation

Differentiation must be made between behavioral and pathologic regurgitation. Behavioral regurgitation is usually done in a controlled fashion and directed at an object in the cage or the owner. Pathologic regurgitation is not controlled and the patient will often sling its head as it regurgitates. Causes for regurgitation include toxicity, especially heavy metal, foreign body ingestion, bacterial, fungal or protozoal gastrointestinal infection, ingestion of oral irritants (ie, biting into a common houseplant of the *Pothos* sp.), goiter in budgerigars, rancid food ingestion, gastrointestinal obstruction, pancreatitis, renal

failure, hepatopathy, septicemia, dehydration, polydipsia, motion sickness and proventricular dilatation disease. Diagnostic tools include radiography (plain film and barium series), blood metal level tests, Gram's stains of fecal, crop or regurgitated material, and culture and sensitivity. Determining and correcting the underlying cause is necessary for long-term treatment. Initial therapy may include parenteral fluid administration, metoclopramide parenterally, crop flushing, frequent gavage-feeding of small amounts of a non-viscous formula.

Gastrointestinal Stasis

The most important aspect of resolving gastrointestinal stasis is to identify the underlying cause. Differential diagnoses include proventricular dilatation disease, bacterial or fungal crop infection, foreign body ingestion, septicemia, gastrointestinal obstruction, toxicity or other underlying disease. The first step in treatment of gastrointestinal stasis is to remove excessive material from the crop if present. A Gram's stain or culture and sensitivity of the flush contents will help yield a diagnosis if primary crop infection is present. Rehydration must be accomplished via parenteral fluids prior to initiating gavage feeding. Once this is accomplished and the crop is empty, the bird should be tube-fed small amounts of a dilute solution such as non-lactated multielectrolyte solution and 5% dextrose or carbohydrate substitute. jk If obstruction is not suspected, gastrointestinal stimulants such as cisapride^p (0.5-1.5 mg/kg PO q 8 h) or metoclopramide (0.5 mg/kg IM q 8-12 h as needed) may improve motility. Although cisapride has been taken off the market in the United States, it is still available through compounding pharmacies. It also is important to note that metoclopramide has been shown to cause seizures in macaws at 0.5 mg/kg; however, when given at 0.1 mg/kg both PO and IM, no hyperexcitability or seizures have been noted by one author (TLL). As gastrointestinal motility improves, tube-feedings can be made more concentrated until normal consistency is tolerated (see Oral Nutritional Supplements in this chapter). Identification and treatment for the underlying cause of gastrointestinal stasis must be accomplished (see Chapter 14, Evaluating and Treating the Gastrointestinal System).

Blood in Droppings

It is important to note whether blood in the droppings originates from the urine, feces, reproductive tract or cloaca. Blood in the urine (see Fig 7.2) is a sign of kidney disease and is commonly caused by toxicity or tumors. Some birds will pass blood in the urine transiently after restraint. This vessel's fragility is not normal and, like occult blood in the feces, may be a sign of liver or gastrointestinal disease. A fecal test^q will identify blood versus artifact.*

(*Ed. Note: The authors have performed tests on 15 clinically normal boarding birds: no blood was grossly or microscopically noted in the stools and all were negative on the occult blood test. It has been stated that all birds' stools test positive for occult blood, however, we did not find this to be true. Positive blood on a fecal in a normal bird may be found when the diet includes meat products.)

Melena is the passage of black, tarry feces containing blood that has been acted upon by the digestive system. This is commonly seen in advanced liver disease, gastro-intestinal ulceration and starvation. It also may be seen with gastric and hepatic adenocarcinoma and pancreatitis. Treatment should include treatment for the underlying cause, vitamin K₁ injections (0.2-2.5 mg/kg IM as needed) and parenteral fluid administration. Tube-feeding with barium sulfate suspension concentration (0.05 ml/g body weight PO as needed) provides a protective and anti-inflammatory coating to the gastrointestinal tract, assuming no perforation exists.

Hematochezia is the passage of frank blood in the feces. Causes include foreign body ingestion, reproductive disease, neoplasia, papillomas, cloacitis and gastroenteritis. The appearance of frank blood that is separate from the fecal portion and the urine portion when multiple droppings are examined is generally either reproductive or cloacal in origin. In South American psittacines, the presence of cloacal papillomatosis should be suspected and a cloacal examination done to rule out this disorder. Frank blood or hemoglobinuria may be seen in the urine in some cases of lead and other heavy metal toxicosis.

Cloacal Prolapse

Cloacal prolapse has been associated with behavior problems (see Chapter 3, Concepts in Behavior, Section III, Pubescent and Adult Psittacine Behavior), poor nutrition, neoplasia, papillomatosis, infection and reproductive complications. Prolapsed tissue should be inspected for necrosis or tears. Viable tissue can be gently replaced using a gloved finger or blunt swab lubricated with activated yeast gel^r. In this author's (GJH) experience, when there is severe tissue inflammation, the topical application of a dexamethasone-dimethyl sulfoxide (DMSO) solution (4 mg:10 ml) will help reduce swelling with no apparent clinical adverse effects; however, inflamed tissue in addition to DMSO may allow systemic uptake of these drugs causing potential adrenal suppression. Hyaluronidase also can be utilized to reduce tissue swelling. Its effect is assumed to last for several days, as has been documented in people (TLL).

Suture placement to reduce the cloacal opening has been described to maintain reduction of a prolapse; however,

if the underlying cause is not corrected, this will be only a temporary solution. In recalcitrant cases (ie, sexual behavior/masturbation), 2-0 nylon may be necessary, as smaller sutures will not hold. Care must be taken to avoid damage to the innervation of the vent. Do not place sutures directly within the vent lips. Do not inhibit defecation by having excessive restriction of cloacal outflow. Cloacal atony associated with these conditions has been reported to respond to cisapride.^{p,39}

Many birds with cloacal prolapse may present for foulsmelling diarrhea. A Gram's stain will often demonstrate overgrowth of clostridial organisms when this fetid diarrhea is present in association with cloacal prolapse and straining. Although the clostridial overgrowth is likely secondary to irritated cloacal mucosa and fecal retention, it still requires treatment when encountered. Gram-negative overgrowth also can occur, and a culture and sensitivity of stool would then be indicated.

More persistent or recurrent prolapses may require a cloacopexy. When the cloacal margins have been excessively stretched, surgical reduction may be necessary to reduce the diameter of the opening (see Chapter 35, Surgical Resolution of Soft Tissue Disorders).

The owner should be forewarned that there is danger of stricture and/or impediment to defecation or urination when a cloacopexy is performed, and unless underlying causes are addressed and corrected, the prolapse is likely to recur.

Uterine Prolapse

Uterine prolapse may occur as a sequel to egg binding or in conjunction with cloacal prolapse. Frequently, an egg will be visualized within the prolapsed tissue. Prolapsed tissue must be carefully flushed with sterile saline and examined for tears and necrotic areas. Treatment includes supplemental heat, warm SC fluid administration, parenteral calcium and broad-spectrum antibiotics. Secondary yeast infections are commonly seen in these cases, so antifungal medication also may be indicated. Once tissue has been debrided and inspected, it can be gently replaced using a gloved finger or sterile swab. However, the suspensory ligament has usually been damaged by the prolapse, and suturing the cloaca to hold the uterus as it involutes or performing a cloacal hysterectomy may be the best approach. Severely necrotic uterine tissue may require resection. Subsequent ovulation would, therefore, potentially allow intracoelomic follicle deposition and egg-yolk peritonitis in some species and individuals. Birds with uterine prolapses frequently have poor prognoses, since they are often malnourished and may have advanced liver disease or other underlying health problems.

Metal Toxicities

Toxicities are frequently seen in birds, especially in those that are allowed to roam freely in the house. Metal toxicity is common, with zinc toxicosis seen most often in the USA. Clinical signs may include general malaise, polyuria and diarrhea, and polydipsia with subsequent passive regurgitation of water. Neurologic signs are more common with lead toxicosis than with zinc toxicity. Radiographs can be helpful in identifying metal particles, however, metallic foreign bodies will not be seen in some zinc-toxic birds.36 Conversely, not all ingested metal is toxic. Placing a bird in a paper bag for radiography facilitates screening for metal densities with minimal stress. Blood metal concentration tests are dependable for the diagnosis of metal toxicosis;35 however, significant blood elevations of metal may not always occur in clinically ill birds. 15 Furthermore, there is disagreement as to what constitutes accurate reference levels for metal toxicities.28 Cases are best diagnosed and treated after careful consideration of history, clinical signs and test results.

Treatment for metal toxicity involves removal of the metal pieces from the gastrointestinal tract and/or chelation of metal ions in the bloodstream. Cathartics, such as lactulose or 1% psyllium in a hand-feeding formula, speed elimination of smaller metal pieces. Oils such as peanut butter are much less effective. Magnets are used in larger birds for removal of sizable iron pieces that have been galvanized with lead or zinc. For chelation therapy, the following drugs are commonly used:

- 1. Injectable edetate calcium disodium injection, USP^t, (CaEDTA) (35 mg/kg IM or IV q 12 h for 5 days, then repeat as needed) is an effective chelator. Its disadvantages include expense, pain at the injection site and potential nephrotoxicity (although this has not been documented in birds to date). The advantage of CaEDTA is that its parenteral formulation allows administration even in birds that are regurgitating.
- 2. Succimer (30 mg/kg PO q 12 h for 14 days) is an oral chelating compound that is safe and effective, especially for lead. It is usually made by a compounding pharmacy into a 25-mg/ml suspension.³⁶
- 3. D-penicillamine^u is the author's (GJH) drug of choice (55 mg/kg PO q 12 h for 1 to 2 weeks, off 1 week, then repeat as needed). It is an oral chelating compound that is safe and effective. However, it is available only as an oral medication, and therefore may not be used for the initial therapy if the patient is regurgitating. Also, it has been reported to cause regurgitation in some birds. Prolonged use may create a copper deficiency.
- 4. DMSA and dimercaprol.

Airborne Toxicities

Superheated, Non-stick Plastic Fume Toxicity

Superheated, non-stick plastic fume toxicity, or polytetrafluoroethylene (PTFE) gas poisoning, can be rapidly fatal. Clinical signs include severe dyspnea, weakness and coma. Treatment should include supplemental oxygen, SC fluids, aminophylline (10 mg/kg IV q 3 h, after initial dose, other doses can be given PO), dexamethasone sodium phosphate (0.8 mg/kg IV once), heparin (40-50 IU/kg IV once) and nebulization with heparin, lactated Ringer's solution and dexamethasone. The prognosis for severely affected birds is extremely poor (see Chapter 31, Implication of Toxic Substances in Clinical Disorders).

Air Fresheners

Clinical symptoms similar to PTFE toxicity have been observed in smaller birds (budgerigars, canaries) after exposure to plug-in or wick air fresheners. Treatment is the same as for PTFE toxicity.

Scented Candles

Sneezing and nasal discharge may occur after exposure to lighted, scented candles. Some scented candles contain wicks made with lead. When these are lit, the resulting odor can be poisonous to birds as well as humans.

Candy Cooking Flavoring

Flavorings such as peppermint and spearmint used in candy cooking while birds were present in the kitchen caused death in two budgies that were located 10 feet from the stove in an open cage (K. Marx, personal communication, 2003).

It is likely that other aerosolized agents may be toxic to birds. Limiting the exposure of psittacines to any aerosolized substance is a reasonable precaution.

General Recommendations for Toxicity

When toxicity is suspected, a complete anamnesis should be collected to determine the substance that is most likely responsible. If the bird is not regurgitating, activated charcoal solution can be given (10-20 ml/kg PO) to prevent or reduce toxin absorption in the gastrointestinal tract. Subcutaneous or IV fluid administration encourages the elimination of toxins through urination. If cholinergic toxicity is suspected, atropine (0.1-0.2 mg/kg IM or SQ q 4 h PRN) is indicated.

Poisoning by plants is infrequently seen; other references including human and veterinary poison control centers are recommended if such a case is encountered.

BEAK, NAIL AND FEATHER TRAUMA

The tip of the upper beak may be cracked without any blood or obvious displacement of the rostral fragment. The bird may present for clinical signs such as decreased appetite, hesitancy to climb or failure to preen and history of a fall or other trauma. When digital pressure is applied to the rostral portion of beak, the distal damaged fragment may shift.

One method of correction is to use an electric grinding tool and hone off the fractured tip. If bleeding occurs, the practitioner may use the grinding stone's heat, or other cautery method, to cauterize the tip of the newly exposed beak. Soft foods may be used for a short period to encourage the bird to eat. It may be best to perform this procedure under a light plane of inhalation anesthesia. Damage to the beak tip is painful, and the anesthesia will prevent elevation of the bird's blood pressure and associated increase in bleeding.

Broken nails are a concern if they bleed excessively. Cutting off any remaining distal portion and cauterizing as discussed above is usually corrective. Similarly, applying flour as a first aid measure may be palliative until attended by a veterinarian. Telephone advice for this condition includes suggesting that the owner place flour in the bottom of a shoebox or other container and place the bird inside. This way, the bird's nail will come in contact with the flour without the increased blood pressure (and subsequent increased bleeding) that can occur with restraint.

Broken and bleeding feathers are handled similarly to the beak and nails. Distal fragments can be removed, and if still actively bleeding, place flour directly on and in the follicle. Ligating the proximal portion of the feather may be necessary. Caution must be used in advising clients to attempt chemical cautery at home. Inadequate restraint and insufficient application of hemostatic agents combined with the increased blood pressure generated by the restrained bird often result in prolonged and repeated bleeding episodes.

Cautery or pulling the broken feather is best avoided if possible. Pulling the feather may result in damage to the feather follicle's generative tissue, resulting in a crooked or cystic feather.

Excessive bleeding from any source should be investigated. Hepatic disease is frequently an underlying cause of coagulopathy.

More severe beak injuries are discussed in Chapter 14, Evaluating and Treating the Gastrointestinal System.

TRAUMA

Head Trauma

This is most often seen in free-flying birds encountering a ceiling fan or sliding glass doors. Cranial trauma may

Fig 7.22 | Micro-encapsulated ammonia solution" for postsurgical or traumatic pain, burns and swelling. It is the author's (GJH) observation that the solution also aids in preventing bacterial overgrowth.

cause neurologic clinical signs. Prednisolone sodium succinate is a rapid-acting steroid that helps decrease central nervous system swelling. Dexamethasone sodium phosphate also can be given (2 mg/kg IM once). Head trauma cases should be placed in quiet, dark places with no heat. Minor cases usually recover within 24 to 48 hours.

Limb or Body Trauma, Bites, Lacerations

Non-penetrating traumas can be greatly aided by the use of a topical ammonia solution^w (Fig 7.22). This product reduces pain, swelling and the incidence of infection. (GJH)

In the case of fractures and deep penetrations, stabilization of the patient is the first priority. If there is no active or severe bleeding, warm, quiet and oxygenation may be the logically provided emergency care. While the bird is stabilizing in the warm, humidified oxygen chamber, the practitioner can be collecting information from the client that will aid in subsequent determination of the location and extent of the injuries, and in their treatment.

If significant active bleeding is present, this must be controlled. The application of direct pressure to the wound for several minutes may accomplish this. Remember that a bird's blood pressure can undergo a threefold increase in response to painful stimuli. Therefore, if the bleeding has stopped, it may be wise initially to refrain from exploring the injured area until the patient is stable (see earlier portion of this chapter). Repeated manipulation and restraint may cause the resumption of bleeding.

If bleeding persists, however, one or more of the following steps should be taken:

- 1. Application of a pressure wrap.
- 2. Radiosurgical cautery.
- 3. Application of ferric subsulfate.
- 4. The use of Yunnan Piao^x, a Chinese herb that also is an excellent hemostatic agent.²⁴ It can be used as a topical agent or mixed with a non-lactated multielectrolyte

- solution and gavage-fed prior to surgery. This decreases blood loss in surgeries where excessive bleeding may occur (GBF).
- 5. Vitamin K₁ injection and evaluation for hepatopathy.

Once bleeding is controlled and the patient is stable, wounds should be debrided and cleaned. Any feathers that are sticking in the wound should be cut or removed. Wounds can be flushed with 50% dextrose for its bacteriocidal properties. Sterile saline also can be used. If there is dirt and dried blood caked in the wound, gentle cleaning with gauze and 0.5 to 1.0% povidone-iodine is helpful. In birds, many wounds will heal very well by second intention without sutures. Patients that pick at their wounds may require a collar.

BANDAGING

Modern gel-type dressings (Figs 7.23a-d) have made bandaging of bird injuries much easier and more successful. When combined with the improved properties of adhesive tapes (see Figs 7.9f,g), bandage removal has been made difficult to impossible for the bird and relatively easy for the veterinarian.

If needed, protective neck devices or collars can augment the bandage for additional safety. The bandages can usually be left on for 2 days. The hydroscopic or gel dressing can be reapplied at the time of bandage change.

Wounds that are deep, extensive or obviously contaminated require parenteral antibiotic administration as well as topical debridement. Puncture wounds, often from dog or cat bites, may appear minor but have a great potential for infection and septicemia.

Split Vent or Ruptured Pygostyle

This condition is commonly seen in malnourished cockatiels and other psittacines, and results from trauma to the region caudal to the vent during a fall (Fig 7.24). When the bird's tail feathers strike the floor, the skin and connective tissue surrounding the vent is stretched to the point of tearing. The skin in malnourished birds is not flexible and it tears easily. These wounds often have significant exposure of the subcutaneous tissue and muscle. Treatment includes debridement and flushing of the wound. Transecting the tail feathers so that they do not touch the floor as readily helps minimize repeated stretching trauma. The bird must be housed so that repeated trauma does not occur. If the wings were severely clipped, they should be allowed to grow out to allow some glide and decrease the severity of impact. Amazingly, these wounds may heal very well without sutures by second intention. In selected patients, suturing may be indicated. Critical to the long-term prevention of recurrence of this condition is changing the

Fig 7.23a | An example of a gel dressing with a biosynthetic absorbent coating^{cc} that helps to maintain wound hydration. This type of dressing does not adhere to skin and is ideal for wounds without appreciable necrotic debris.

Fig 7.23c | A section of the gel dressingd^{dd} has been cut into the desired shape and the protective backing is removed. The red necrotizing tissue of Amazon foot necrosis is readied for the bandage with the bird under anesthesia.

bird's diet to correct the malnutrition and obesity that were contributing factors.

ACUTE BLOOD LOSS AND ANEMIA

Acute blood loss is more rapidly life threatening in malnourished birds because they frequently have decreased liver function with associated coagulopathies. Severely anemic birds will appear pale on the skin covering the nares and feet, and have pale mucous membranes of the cloaca and oral cavity. Tachypnea and tachycardia also may be present.

As with other species, the administration of oxygen will increase the efficiency of the remaining red blood cells.

Fig 7.23b | A hydroactive dressing^{dd} is soft and spreads out as it absorbs serum from a wound and molds to the area. This "gel" is an excellent debriding agent and also forms a matrix in which cells can grow. If there is copious serum production, the bandage should be changed daily. To apply, the protective backing of the dressing is removed and the yellow-brown gel side is applied to the wound. A flexible bandage as is then applied over the dressing.

Fig 7.23d | The H-shaped dressing is placed on the plantar surface of the claw. The four legs of the H fold around the metatarsus and the third digit, covering all surfaces of the wound. A coating of a cohesive, flexible bandage and an over-covering of elastic-cloth tape² is applied as shown in Figs 7.9 f,g.

Fig 7.24 A cockatiel with a split in the tissue just caudal to the cloaca's yellow feathers. This is a sign of a nutritional disorder that has diminished the skin's elasticity. Improvement of the bird's diet, preventing the bird from falling on hard surfaces and treatment as an open wound are indicated.

Transfusions are indicated when the packed cell volume (PCV) is below 20%. Homologous transfusions, from the same genus and species, yield the best result.^{7,8} Transfusion volume should be 10 to 20% of the patient's calculated blood volume.

Studies showed that using washed RBCs (no plasma) in conures the same genus as a donor was as efficacious as homologous transfusions (white-eyed conure to sun conure, sun conure to sun conure) for a single transfusion.⁸ In another study, however, cockatiels received Amazon blood (a heterologous transfusion), and these washed and labeled RBCs were short-lived.⁷

Other alternatives for blood transfusions have recently become available. Hemoglobin glutamer-200 (bovine) (Oxyglobin^y) (30 ml/kg IV once) has been shown to be effective in the resolution of clinical signs in dogs, cats, sheep, rats, horses and a number of exotic animals.²⁷ Its use in avian medicine has been investigated,²⁰ although it is not labeled for use in birds. Hemoglobin glutamer-200 is expensive due to the lack of availability of small packaging, but it is potentially useful in treating avian anemia.

Hetastarch

Hetastarch (10-15 ml/kg IV q 8 h up to 4 treatments)^{4,20} is used primarily for intravascular volume restoration; however, it can be used in anemic patients when blood products are unavailable.²⁹

Erythropoieting

Erythropoietin^g (100 IU/kg SC 3 times per week until desired PCV is attained) has been reported to improve success in treating chronic anemia by stimulating erythrocyte production in some mammals.²⁹

Erythropoietin⁸ is a hormone that stimulates erythropoiesis in severely anemic patients. Avian erythropoietin, which is stimulated and released following hypoxia and suppressed by induced polycythemia, is structurally different than the mammalian type. Whether or not mammalian erythropoietin acts to stimulate RBC production in birds is not documented.

Interferon and F10

In the United Kingdom, preliminary results of clinical trials on circovirus-positive African greys with precipitous decreases in WBC and RBC counts show promise using interferon, F10^{ec}, and Oxyglobin^y injections (M. Stanford, personal communication, 2003).

As with all critical conditions in birds, the stress of treatment must be considered prior to initiating intensive therapy. Birds with severe anemia have little oxygen

reserve, and treatment that causes stress with increased oxygen demand may prove fatal.

FRACTURES

In cases of fractured limbs, it is a priority to stabilize the patient before attempting fracture repair. Birds will die from stress, anesthesia, debilitation or septicemia rather than from the fractured limb. Topical analgesic^w (Fig 7.23) helps reduce soft tissue swelling and pain. Analgesics such as butorphanol are indicated for systemic pain relief in fracture patients (see Chapter 8, Pain Management).

For emergency care of fractures, bandaging, and fracture repair see Chapter 34, Surgical Resolution of Orthopedic Disorders.

Pain Management

JOANNE PAUL-MURPHY, DVM, Dipl ACZM

Fig 8.1 | With such a devastating lesion, pain would seem obvious, but the canary did not show evidence of pain until this band was removed.

What is Pain?

The International Association for the Study of Pain (IASP) defines pain as an unpleasant sensory and emotional experience associated with actual or potential tissue damage.² The IASP also includes under this definition an important note: *The inability to communicate in no way negates the possibility that an individual is experiencing pain and is in need of appropriate pain-relieving treatment* (Fig 8.1). This is a very important statement that gives credibility to pain experienced by non-verbal populations of species, including humans as well as all animal species.

All animals have neuroanatomical and neuropharmacological components required for nociception: transmission, perception and response to noxious stimuli. But when does nociception become pain? This is not easily determined, but for the purposes of this chapter it will be accepted that not only do birds perceive and respond to noxious stimuli, but also that birds feel pain. Pain is always subjective and the emotional component is difficult for us to translate because birds do not share a verbal language with humans. In humans, we accept that pain is what the patient says it is, but in birds as well as other animal species, it is what people think it is.

RECOGNIZING PAIN

The challenge is to recognize avian behaviors that occur with painful stimuli, both acute and chronic. Perhaps birds have evolved behaviors to minimize painful displays as a way of minimizing the attention of predators. We are not yet fully capable of recognizing when a bird is affected by pain; therefore, it may be best to err on the side of over-estimation and assume that conditions that would be painful to humans also are painful to

birds. Nonetheless, having an identified behavior or set of behaviors that correlate with pain provides a means to monitor response to pain treatment. It is difficult to say we have effectively treated something if we cannot measure it before and after therapy. But there is no reliable measurement or gold standard for the assessment of pain in animals, including birds, either for research subjects or clinical patients. Assessment of pain must give consideration to species, gender, age, strain, environment and concurrent disease. Significance must be given to the type of pain, such as acute, chronic, somatic, visceral, clinical or neuropathic.

Behaviors that occur with acute noxious stimuli are the easiest to identify. There is an immediate cause-effect relationship between activation of nociceptors (a receptor preferentially sensitive to a noxious stimulus), withdrawal reflexes and behaviors that correspond to conscious perception of the stimulus.12 Noxious stimuli that have been used to study avian pain are similar to those used in mammalian studies, such as electrical stimulation, thermal stimulation and pressure, but other studies have employed noxious stimuli unique to birds, such as feather removal, beak amputation and comb pinching, as well as research models for chronic pain using intra-articular injection of sodium urate. 12,18 Physiological measurements are not always consistent or specific to painful stimuli and are not useful for assessment. Respiratory rate, heart rate and blood pressure will increase during painful stimuli but also can be affected by light, sound, temperature, restraint and other external stimuli. Avian withdrawal behaviors to acute painful stimuli include escape reactions (foot lifting, wing flapping), vocalizations, decreased head movements or extreme movements (jumping). When parrots were given a mild electrical stimulus to the foot using a specially designed test perch, the expected response was foot withdrawal with a reluctance to place the foot back on the perch; but there also were several individual parrots that did not lift the foot, but began flapping their wings when a stimulus was delivered.31 Chickens can display a distinctive behavior termed crouching immobility, which occurs experimentally when they are exposed to repeated noxious stimulation. 12,14,37

How do we know when a bird is experiencing prolonged pain or chronic pain? It is generally accepted that when a bird is in pain there is a change in or absence of one or more normal behaviors. To accurately assess pain, the observer must be familiar with normal and pain-associated behavior of a given species of bird as well as that of the individual bird. Social species of birds will decrease their social interactions. This may be as subtle as a reduction in social grooming behaviors or as obvious as perching away from the flock. For social species of birds housed as single pets, there may be a reduction in inter-

actions with the owner. This is often manifested by a decrease in vocalizations or chattering that birds often do with the owner or reluctance to seek stroking or petting from the owner. Guarding behavior to protect a painful body part is seen in birds and can subtly manifest in similar antisocial behaviors. Aggression has been linked in individual birds to painful conditions because often the aggressive behaviors dissipate once the clinical problem is resolved. A behavioral change in feather grooming is common to both solitary and social birds. The change can be either an increase or decrease in grooming. Decreased self-grooming is a withdrawal behavior that occurs when a bird's focus is on pain and not daily activities. Increased grooming behavior to themselves or other birds in their environment can be an intentional distraction. Studies using chickens with induced sodium urate arthritis demonstrate that shifting attention can reduce the severe pain and potentially reduce peripheral inflammation. 13 Alternatively, grooming and feather picking may increase over a specific area, often directly related to the region of discomfort or painful stimulus.

Decrease in appetite and weight loss often accompany painful conditions. In a study of rats observed postoperatively, dehydration and weight loss due to decreased food and water consumption was significantly lower in rats given adequate perioperative analgesia. Unfortunately, dehydration and weight loss can occur under numerous stressful conditions, from something as simple as changing the perches in a bird's cage to a variety of known diseases. Weight loss is not unique to pain, but because it can be quantified it is very valuable to record a bird's daily weight. If weight gain or stabilization occurs following administration of analgesia, then it was a useful gauge.

Tonic immobility is an innate fear response characterized by a profound and reversible state of motor inhibition. In chickens, crouching immobility has been associated with prolonged pain, stress and fear responses. Studies using chickens demonstrated that repeated feather plucking caused an initial agitated response, which progressed to sustained crouching immobility of the chicken. 12,14 A later study using chickens with ulcerated oral lesions placed an irritating substance on the lesions, which caused several birds to go into a crouch-like posture, with the head held close to the body and a significant reduction in head movements.11 The immobility reaction is prolonged when fear is present and reducing the fear component decreases the time of immobility. Companion birds may display similar tonic immobility postures postoperatively or under chronically painful conditions. It has been suggested that tonic immobility evolved as a response of a prey species to reduce potential damage produced brought on by struggling. In

guinea pigs, it has been demonstrated that tonic immobility induces an endogenous analgesia involving opioid synapses, which increases the animals' threshold to noxious stimuli.²¹

The correlation of elevated corticosterone has been studied in its relationship to pain. It is a hormonal indicator known to become elevated with ACTH (adrenocorticotropic hormone) release and stress in birds and other animals.²⁴ Pain can induce both acute and chronic stress. Fecal corticosterone levels may offer a measurable response that can be collected without interfering with the bird's normal activities.²² Studies are currently in progress to determine if measurable amounts of corticoids in avian feces correlate to painful stressors.

PAIN ASSESSMENT SCALES

Pain assessment scales are used in human medicine for verbal as well as non-verbal segments of the population. Pain scales can be sensitive and repeatable, and a similar process could be used to develop pain scales for birds with the understanding that each would have to be species-specific. As an example, a recent study with pigeons noted that body trembling consistently occurred for several hours after recovery from general anesthesia, orthopedic surgery and opioid analgesia, but it did not occur with controls given the same period of general anesthesia and opioid, but without orthopedic surgery. Additionally, all pigeons received the opioid after surgery, but the group of pigeons that also received opioids prior to surgery stopped trembling earlier in the recovery period than the other surgical group (J. Paul-Murphy, unpublished data). Body trembling may be specific to pigeons or it may be specific to orthopedic surgery, or it may be specific to some other variable not measured in this early attempt to develop a pain scale for pigeons. There are currently more than 26 published pain scales for children, each trying to manage variables that may confound pain assessment.23 A pain scale can be a very useful assessment tool under consistent conditions, and it may be necessary to develop numerous species-specific scales until a more accurate method is found to assess pain.

PHYSIOLOGY OF PAIN

The physiology of pain in all animals involves the peripheral process of detecting a noxious stimulus (mechanical, thermal or chemical) and transmission of the impulses to the spinal cord. Here they are modulated and projected to the brain for central processing of the information, which determines the perception of the noxious stimulus. Nociceptive pain involves the activation of the pain receptors, is usually localized and transient, and usually activates a withdrawal response, both reflexive and con-

scious. All other types of pain are considered clinical or pathological, often involving tissue damage with inflammation or nerve damage. Pathological pain can originate from a gentle tactile stimulus, causing an exaggerated or prolonged pain response, or can persist in the absence of noxious stimuli.

Peripheral sensitization occurs when inflammation at the site of injury creates an increased response to a normally painful stimulus. Cell damage and leakage leads to a series of responses resulting in increased sensitivity of the peripheral receptors and may even activate "silent" nociceptors, which magnify the pain response. In addition to sensitization at the peripheral tissue and pain receptor environment, the central nervous system can be sensitized as well. Central sensitization is an increase in the excitability of spinal cord neurons and a recruitment of neurons not involved in pain perception under normal circumstances. When stimulation from the peripheral nociceptors to the spinal cord continues for an extended time period, a wide range of spinal neurons become sensitized and hyper-responsive. The response to additional noxious stimuli becomes heightened and prolonged. Stimulation from the periphery that was previously nonnoxious, such as a tactile stimulus, becomes painful.

Understanding the mechanism of peripheral and central sensitization helps to explain why prevention of sensitization is critical and provides multiple places in the process that could be altered by different classes of analgesic therapy. When sufficient analgesia is provided at an early stage of tissue trauma, such as with surgery, it can greatly reduce the degree of postoperative discomfort.33 Although this has not been experimentally demonstrated in birds, animal and human studies have demonstrated that when analgesics are given prior to a painful event rather than after the start of the stimulation, the spinal excitability can be dampened.35,36 The earlier pain is treated, the less total drug will be required to maintain analgesia both during and after surgery. It has been shown in mammalian species that a shorter period of analgesia is needed in the postoperative period when analgesics are given in the preoperative period.³³ A study of pigeons undergoing orthopedic surgery showed that the pigeons receiving butorphanol before and after orthopedic surgery returned to normal behaviors sooner than those pigeons receiving butorphanol only in the postoperative period (J. Paul-Murphy, unpublished data).

RELIEF OF PAIN

Pain is a combination of both peripheral inputs and neurophysiological processes within the central nervous system. Diagnosing the cause of pain can be difficult at times, but identifying the disease process or site of tissue damage will influence the choice of analgesic drugs

and supportive care. Therapy should be directed at resolving the disease process or injury as well as reducing pain signals coming from the periphery and its effects on the central neural processing of the pain. For example, immobilizing a bird's fracture maximizes bone healing, but it also reduces micromovement irritation and inflammation, thus reducing noxious stimuli projected from the site of trauma. Analgesia therapy may include an opioid plus an NSAID, but the immobilization itself greatly reduces the pain. Conversely, we may recognize the signs of pain in a patient before we actually diagnose the cause, and in these cases, treatment of the pain becomes part of the symptomatic approach to therapy. Selection of analgesic drugs should be done conservatively in situations where the cause of pain is still under investigation.

Supportive care is very important to the management of pain. This includes keeping the avian patient warm, dry and clean. Environmental stressors should be kept to a minimum by providing a quiet, soothing hospital environment away from barking dogs or strong smells of "predators," such as cats and ferrets. If the bird is a pet, provide human contact and speak in a soothing voice.

Pharmacological Approach to Pain Control

LOCAL ANESTHETICS

Local anesthetics are used to produce regional anesthesia and analgesia by blocking the transmission of noxious impulses. Local anesthetics such as lidocaine and bupivacaine block sodium channels in the nerve axon, which interferes with the conduction of action potentials (pain impulses) along the nerve. Reducing the number of pain impulses reduces the nociceptor sensitization, which has the beneficial effect of minimizing central sensitization. Local anesthetics do not need to be distributed systemically for the analgesic effect, but will slowly be absorbed by the vasculature in the region being blocked.

Regional infiltration or a local line or splash block are among the most common methods used. A 25-gauge needle is used to make several subcutaneous (SQ) injections of small volumes of dilute solution into the operative area. A line block follows the course of the intended incision by injecting a modicum of dilute anesthetic SQ, then withdrawing the needle and reinserting it at the edge of the raised area. Another modicum is delivered under the skin and the process is repeated until the length of the incision is blocked.

Lidocaine has a commercial preparation of 2% (20

mg/ml), and the formulation without epinephrine is recommended. The commercial preparation should be diluted 1:10 with sterile water or diluted further to the volume required for the block. The total dosage should not exceed 2 to 3 mg/kg. For example, a 500-g cockatoo can receive 1 mg lidocaine; 0.05 ml is diluted to 1 ml and this solution is used to block a 2-cm surgical skin incision. The commercial preparation of bupivacaine is prepared as 0.25% (2.5 mg/ml), 0.5% (5 mg/ml) or 0.75% (7.5 mg/ml) solution. No bupivacaine dosage has been established for birds, but 1 mg/kg total dose has safely been administered to large birds.

Local anesthetic dosage recommendations for birds are lower than for mammals because birds may be more sensitive to the effects of the drug. Systemic uptake of the drug may be rapid in birds, increasing the potential for onset of systemic reactions. There can be acute toxic effects if these drugs are accidentally injected intravenously. Toxic side effects can include fine tremors, ataxia, recumbency, seizures, stupor, cardiovascular effects and death. Chickens were injected with high doses of bupivacaine (2.7-3.3 mg/kg) and showed immediate signs of toxicity such as drowsiness and recumbency.¹⁸

The duration of action of local anesthetics depends on the molecular properties of each drug, especially the lipid solubility of the drug. Neither the time to effect nor duration of action has been determined for these drugs in birds. In mammals, bupivacaine lasts much longer (4-10 hours) than lidocaine (1-3 hours).

Intra-articular administration of bupivacaine (3 mg in 0.3 ml saline) was studied for its analgesic effects in chickens with experimentally produced acute arthritis. Chickens given bupivacaine were able to feed, peck and stand on the affected limb similar to birds without arthritis. ¹⁸

Topical benzocaine has been used for minor wound repair in small birds.³ Topical bupivacaine has been studied when applied to the amputation site in beaktrimmed chickens and provided 4 hours of analgesia.¹⁶ In mammals, local anesthetics also are used in the form of transdermal patches and transdermal creams, but the use of these patches and creams has not been studied with birds. Local anesthetics also are used in mammalian medicine for epidural infusions, spinal blocks, intravenous blocks and peripheral nerve blocks and as an antiarrhythmic agent, but none of these applications has been reported for use in birds.

OPIOIDS

Opioids reversibly bind to specific receptors in the central and peripheral nervous systems. There are three major classes of opioid receptors associated with analge-

sia: mu, delta and kappa. Chickens have similar proportions of each receptor type as do humans.7 The distribution, number and type of opioid receptors are conserved across species in the brainstem and spinal cord but vary substantially in the forebrain.²⁷ In mammals, mu and kappa receptors primarily are associated with pain relief, with mu receptors being widely distributed in the forebrain, midbrain and hindbrain, whereas, delta and kappa receptors are numerous in the spinal and supraspinal regions of the central nervous system (CNS). Autoradiography was used to identify mu, kappa and delta opioid receptors in the forebrain of rats, mice and humans, and kappa receptors represented 9, 13 and 37% of the total opioid receptor population, respectively. In contrast, the forebrain of pigeons has a relatively high proportion (76%) of kappa receptors.²⁷

All drugs in the opioid classification have morphine-like effects, which may be mediated primarily by an increase in serotonin synthesis. Given at appropriate dosages, opioids do not cause a loss of consciousness but can cause sedation and respiratory depression. Opioids vary in their receptor specificity and efficacy at different receptors, which results in a wide variety of clinical effects in different mammalian species, and is influenced by the commercial preparation of opioid, the dose and the species receiving the drug. It stands to reason that the opioid and the dose also will have a wide range of clinical effects in different avian species.

Physiological and analgesic effects of opioids have been studied in parrots using the isoflurane-sparing technique. This method anesthetizes healthy birds with isoflurane and determines the minimum anesthetic concentration (MAC) by using a noxious stimulus (toe pinch) and observing a withdrawal response with a cognitive body movement. Each bird then is injected with an analgesic and the MAC is redetermined. If the concentration of isoflurane can be lowered, then this "sparing effect" is considered due to the analgesic effects of the drug being tested. Butorphanol (1 mg/kg) was administered to three species of parrots, and the isoflurane MAC could be significantly lowered in cockatoos and African grey parrots but not Amazon parrots.^{5,6} The addition of butorphanol also caused lowering of the heart rate, tidal volume, and inspiratory and expiratory times. A similar type of study compared mu and kappa opioids in chickens, and both drugs had isoflurane-sparing effects.4

The effect of different opioids on conscious parrots was evaluated by studying the change in withdrawal threshold from noxious electrical and thermal stimuli before and after receiving an opioid. Butorphanol, 1 and 2 mg/kg IM, had an analgesic effect on African grey parrots, and 1 and 3 mg/kg had an analgesic effect on

Hispaniolan Amazon parrots.^{30,31} Plasma concentration of 2 mg/kg butorphanol in African grey parrots has a mean residence time of less than 2 hours (J. Paul-Murphy, unpublished data). Buprenorphine at 0.1 mg/kg IM in African grey parrots did not show an analgesic effect when tested by analgesimetry, but recent pharmacokinetic analysis suggests that this dose may not achieve effective plasma levels, and the mean plasma residence time is only 1 hour (J. Paul-Murphy, unpublished data). Higher doses of buprenorphine using different avian species may help to clarify if buprenorphine is an effective analgesic for birds. Clinical use of buprenorphine suggests it has an analgesic effect.

Fentanyl was evaluated using cockatoos and, although 0.02 mg/kg provided plasma levels similar to the concentration found to be analgesic in cats, it did not affect the withdrawal response of the cockatoos.³⁰ A ten-fold increase in the dosage of fentanyl (0.2 mg/kg SQ) did produce an analgesic response, but many birds were hyperactive for the first 15 to 30 minutes after receiving the high dose.³⁰ The duration of analgesic effect from fentanyl has not been established, but 0.02 mg/kg given IM to cockatoos maintained a plasma concentration considered analgesic in people for 2 hours.

Butorphanol (1-3 mg/kg IM) is the current recommendation for opioid analgesia in parrots. Butorphanol is a mixed agonist-antagonist with primarily kappa agonist action. This supports the one study finding of a high percentage of kappa receptors in the forebrain of pigeons. The dosage of butorphanol for effective analgesia needs to be balanced with sedation and respiratory depression, which may vary with other avian species and need further evaluation.

NSAIDs

Non-steroidal anti-inflammatory drugs (NSAIDs) are among the most commonly used classes of drugs in small animal medicine. NSAIDs interfere with eicosanoid synthesis by the inhibition of cyclooxygenase (COX) enzymes. COX enzymes initiate a cascade of reactions that results in polyunsaturated acids being converted to eicosanoids such as prostaglandins and thromboxane.³⁴ These are released at sites of tissue injury and cause inflammation and sensitization of nerve endings.

Reduction of prostaglandins and thromboxanes decreases inflammation at the site of injury and also has a modulating effect within the CNS. The physiological mechanisms involving prostaglandins, their role in inflammation and their ability to sensitize sensory neurons to physical or chemical stimuli in birds are similar to those in mammals.²⁹ The COX-1 enzyme is part of normal cell composition in numerous tissue types and the

concentrations are fairly stable, keeping prostaglandin levels at homeostatic levels. In mammals, COX-2 concentrations increase when stimulated at sites of inflammation, but both COX-1 and COX-2 are expressed in the CNS and participate in spinal pain transmission. The relative expression of COX-1 and COX-2 enzymes varies among species, and both enzymes are important in avian pain at the site of peripheral inflammation as well as in spinal pain transmission. However, more information is needed to differentiate their physiological effects in avian species.

NSAIDs can be used to relieve musculoskeletal and visceral pain, acute pain (trauma or surgical) and chronic pain such as osteoarthritis. The most common NSAIDs used in avian medicine are piroxicam, carprofen, ketoprofen and meloxicam. These compounds vary in their structure, but all inhibit COX enzymes. Generally, the current NSAIDs are safe drugs but should be monitored and evaluated in each individual patient. Increased monitoring may be indicated with high-risk patients: establishing a base-line set of hepatic enzymes and uric acid prior to NSAID administration and reevaluating these parameters at fixed intervals (see Chapter 16, Evaluating and Treating the Kidneys). NSAIDs should not be used if there is any indication of renal impairment, hepatic dysfunction or severe hypovolemia or if gastric ulceration is present. Only one NSAID should be used at a time, but in cases of chronic pain, frequently review the response to therapy and change to a different formulation NSAID if response is poor or diminishing. For treatment of mild to moderate chronic pain, NSAIDs can be given on an asneeded basis. The dose and frequency of administration has not been determined for any clinical NSAID use in birds. Ketoprofen (5 mg/kg IM) administered to ducks anesthetized with isoflurane had an analgesic effect 30 to 70 minutes after administration.²⁵ Carprofen given to rapidly growing chickens with chronic lameness improved their ability to walk and navigate a maze.28 Carprofen (1 mg/kg SQ) given to chickens raised their threshold to pressure pain for at least 90 minutes.8 Peak plasma levels occurred at 1 to 2 hours after SQ administration of carprofen to chickens.28 Plasma levels do not provide sufficient information to indicate physiological activity of the NSAID because NSAIDs tend to accumulate in areas of inflammation. In mallard ducks, 5 mg/kg flunixin and 5 mg/kg ketoprofen suppressed thromboxane B, levels for 12 hours, indicating a prolonged physiological effect.26

MULTIMODAL THERAPY

Information specific to birds is minimal, and many current therapies for birds are extrapolated from species in a different class of vertebrates. Some drugs are handled similarly across species lines and other drugs may have very different mechanisms of action; they may be effec-

tive in one species and range from ineffective to toxic in another species.

Combining analgesics that act by different mechanisms can maximize the analgesic effect. Administration of two or more analgesics frequently produces a synergistic effect, such as a local anesthetic at the surgical incision or site of recent trauma, a NSAID plus an opioid. This combination of drugs usually allows the dosage of each drug to be reduced, thereby reducing the side effects. Additionally, opioids such as butorphanol will reduce the concentration of inhalation anesthetic needed for a surgical plane. Adjunctive drugs, such as tranquilizers used in conjunction with analgesic drugs, can potentiate the analgesic effects by reducing anxiety. The most common sedatives used in avian medicine are the benzodiazepines, which calm the bird and may reduce anxiety.

CHRONIC PAIN

Treatment of chronic pain in birds opens more questions than there are answers. How to treat chronic pain in a non-verbal patient such as the bird is the ultimate challenge. It is difficult to evaluate response to treatment when the condition itself may be progressive, such as chronic degenerative joint disease or neoplasia. Response to analgesic therapy is based on evaluation of a set of behaviors particular for each individual bird.

NSAIDs are the first course of therapy for chronic disorders. Carprofen is the current drug of choice because of its widespread use and low incidence of reported toxicities. Carprofen is an orally administered drug and can be initiated at the low-end dosage and monitored for response to treatment. As pain gradually increases over time, the dosage of carprofen can be increased, and monitoring the renal and hepatic serum values every 2 to 4 months is recommended, especially in an older bird. If pain recurs over several months of treatment, the next set of options includes changing to another NSAID, such as meloxicam or piroxicam. There is a risk when switching NSAIDs that the side effects can be potentiated, so a no-drug period of 7 to 10 days is recommended. Piroxicam may have synergistic action with anticancer drugs and also is an effective NSAID for degenerative joint disease in birds. Piroxicam is noted for renal toxicity and gastric ulceration in mammals, but its long-term use (months of treatment) in cranes with chronic degenerative joint disease has not caused clinical problems. If pain persists or increases, especially with neoplasia, opioid therapy may be indicated. Unfortunately, most parenteral forms of opioids reach "effective" plasma levels rapidly, but these levels are maintained for only a few hours. No information is available regarding oral opioids in birds. but in mammals much higher dosages are required for oral administration to reach effective plasma levels.

q5d	every five days
q5d-QW	every five days to every week

Abbreviation	Translation
q5h	every five hours
q5min	every five minutes
q60h	every sixty hours
q6d	every six days
q6m	every six months
q6m-QA	every six months to every year
q6w	every six weeks
q7w	every seven weeks
QA .	every year
QD	every day
QD-BID	every day to two times daily
QD-q2d	every day or every two days
QD-q3d	every day to every three days
QD-QID	every day to four times daily
QD-QW	every day to every week
QD-TID	every day to three times daily
QH	every hour
QID	four times daily
QM	every month
QM-q2m	every month to every two months
	every other week
qow QS	·
QW	add sufficient quantity
	every week
QW-q10d	every week to ten days
QW-q2w	ever week to every two weeks
QW-q3w	every week to every three weeks
r10d	repeat in ten days
r2m	repeat in two months
r2w	repeat in two weeks
r6m	repeat in six months
r7-10d	repeat in seven to ten days
ra	repeat annually
rm	repeat in one month
rw	repeat in one week
sc	subcutaneous
SCJ	subconjunctival
SC-Topical	subcutaneous or topical
sec	second
short	short therapy regimen
slowly	administer slowly
soln	solution
TD	total dose
TID	three times daily
TID-q2d	three times daily to every two days
TID-QID	three to four times daily
topical	apply topically
vapor	vapor in enclosure
vent	anus, rectum or cloaca
w	week
weeks	for several weeks
у	year
μg	microgram

Integrative Therapies

ROBERT D. NESS, DVM

Ed. Note: According to the American Holistic Veterinary Medicine Association, "...the word 'holistic' means taking in the whole picture of the patient – the environment, the disease pattern, the relationship of pet with owner – and developing a treatment protocol using a wide range of therapies for healing the patient." This includes integrating conventional protocols with possible complementary and alternative therapies – whatever are the most efficacious, least invasive, least expensive and least harmful paths to cure. The chapter presented here is a brief introduction to selected integrative therapies in order to familiarize the avian practitioner with those that have been used in pet bird practice and to offer options for possible further study.

Integrative therapies constitute a very wide range of disciplines from around the world. Many of these therapies can be utilized to treat pet birds, although none was specifically developed for avian species. Because birds have not been domesticated, remaining genetically and evolutionarily close to their wild counterparts, they tend to be very responsive to natural therapies. Certain modalities, such as chiropractic and acupuncture, must be modified for differences in avian anatomy and physiology. Others can easily be extrapolated to pet birds from human or other mammals with only slight adjustments. Some examples include homeopathy, flower essences, nutriceuticals and many herbs. Other therapies, such as diffusion aromatherapy, must be used with caution to avoid toxic reactions. Integrative therapy in birds has existed for centuries in poultry medicine through acupuncture and herbal therapy in China.

Many terms have been used to describe these forms of treatment, including integrative therapy, alternative therapy, holistic care and complementary medicine. Each of these terms has specific implications and none of them is entirely accurate. Alternative therapy suggests another way to do the same thing. Complementary implies that it augments conventional therapy. Holistic refers to treatment of the whole patient in a complete approach, but usually infers that it is separate from conventional therapy. Integrative therapy involves the integration of a variety of modalities into a more complete healthcare system. This term is most appropriately applied when the varying therapies are used in conjunction with conventional Western therapy.

Several integrative modalities are described below, with specific indications for birds. This is not intended to be an exhaustive list of therapies for birds or serve as a complete description of these therapies. Rather, this is an introduction into the wide array of holistic modalities and their potential implications for pet birds. Further training and education is recommended prior to widespread implementation of these therapies in practice. Veterinary certification programs are available for some of these modalities, including animal chiropractic and veterinary acupuncture. A list of resources and programs is provided in Table 10.6.

Integrative Modalities

ANIMAL CHIROPRACTIC

The practice of chiropractic is credited to D.D. Palmer during the mid-1890s.²⁷ D.D. Palmer's son, B.J. Palmer, further developed the practice through research and clinical practice. Although the Palmers are known as the founders of current chiropractic care, adjustments have been used for thousands of years. B.J. Palmer established the first chiropractic school in Davenport, Iowa, known as Palmer Chiropractic College.

Chiropractic is defined as "that science and art which utilizes the inherent recuperative powers of the body and deals with the relationship between the nervous system and the spinal column, including its immediate articulations, and the role of this relationship in the restoration and maintenance of health."²⁷ Because all functions of the body are innervated and controlled by nerves, the implications of chiropractic care in health management are enormous. Not only can chiropractic therapy treat a stiff neck or back pain, it may be useful in many systemic and metabolic disorders.

Chiropractic therapy is directed at the release of fixations and subluxations of the spine. The term subluxation is used to describe a misaligned vertebra that is unable to properly move in relation to adjacent vertebrae. This can be either a structural or functional malalignment, which may not be obvious on radiograph or conventional physical examination. These subluxations are corrected by a precise manipulation of the spine known as an adjustment. An adjustment involves the application of a high-velocity, low-amplitude manual force to release fixations without damage to the motor unit.²⁷ A motor unit is defined as two adjacent vertebrae and the associated structures between them, including ligaments, blood vessels, nerves, joints and muscles. The adjustment must be specific in regard to the force and angle applied to the specific vertebral joint.

In general, any vertebrate is a potential chiropractic patient, including birds. The avian skeletal system is

unique from those of mammals in several ways. Birds are bipedal with modified forelimbs as wings. Many of the long bones in their limbs are pneumatic, allowing for extension of the air sac system as well as less weight for flying. The air sacs also may perfuse certain segments of the vertebral spine. The avian spine is divided into cervical, thoracic, synsacral, free-caudal and pygostyle (fused-caudal) sections.20 The number of cervical vertebrae varies with species, with budgerigars having 11 and Amazon parrots having 12. The last cervical vertebrae and first 3 thoracic vertebrae are fused in Galliformes. The number of thoracic vertebrae varies from 3 to 10. depending on species. Ribs are present on both cervical and thoracic vertebrae. A large portion of the avian spine is fused into the synsacrum, including the lower thoracic, lumbar, sacral and caudal spine. There are 10 to 23 synsacral vertebrae and 5 to 9 caudal vertebrae. The ilium and ischium are fused together and to the synsacrum. The pubic bones are unfused, except in ratites.

Chiropractic care can be used in a variety of avian cases from trauma to reproductive conditions. Traumatic injury to the cervical vertebrae is a sequela to flying into a wall or window. Torticollis and localized feather picking also can be potential chiropractic cases. Adjustment of the thoracic spine may correct certain respiratory or digestive disturbances with underlying neurologic or neuromuscular origin. Dystocia can be the result of an abnormal egg, metabolic disturbance or abnormal pelvic anatomy. The latter etiologies may be assisted by chiropractic adjustment.²²

VETERINARY ACUPUNCTURE

Acupuncture has been used for at least 5000 years in China, which is considered the site of origin. Early acupuncture needles were made from stone and fish bones. About 500 A.D., the practice of acupuncture spread to Japan and Korea, which established their own forms. By the 6th century, acupuncture had spread throughout Asia. By the 17th century, it was found in Europe, and finally arrived in North America during the 19th and 20th centuries. It was not until 1971 that acupuncture made its way into American culture. This was the result of a New York Times journalist being treated with acupuncture while on assignment in China. He had his appendix removed and was treated with acupuncture for postoperative pain. Over the past 30 years, acupuncture has slowly become more mainstream in American culture.

Veterinary acupuncture also has a long history. Evidence of elephant acupuncture dates back about 3000 years in Sri Lanka. The Chinese Chou Dynasty dating back to 1066 to 221 B.C. recorded several veterinary applications. The father of Chinese veterinary medicine is Shun

Yang (Pao Lo), who was the first full-time practitioner of Chinese veterinary medicine in 430 B.C.³¹ Veterinary acupuncture has developed in various parts of the world, especially in Asia, over the past 2000 years. In 1974, the National Association of Veterinary Acupuncture (NAVA) was established as the first veterinary acupuncture association in the West, but was active for only 5 years.¹⁰ Later in 1974, the International Veterinary Acupuncture Society (IVAS) was established and has since become a core association for veterinary acupuncture in the United States and the world. Since 1998, three other teaching organizations in the USA have offered training in veterinary acupuncture.

Acupuncture is one part of the holistic health system known as Traditional Chinese Medicine (TCM). Other TCM components include proper nutrition, exercise, herbal remedies and appropriate lifestyle. The main premise of TCM is that we are all part of nature, and health is achieved by establishing balance with the natural world. This balance of nature is characterized by the Chinese concept of Yin-Yang, which is the balance between such things as light and dark, wet and dry and hot and cold.

Acupuncture involves the placement of fine needles into specific points on the body to elicit a physiologic and energetic response along energetic pathways known as meridians. Meridians are interconnected energetic pathways that run throughout the body. These pathways carry the body's Qi (vital life force or energy). The presence of Qi is what defines the existence of life. The placement of acupuncture needles into points along these meridians enables the body to restore itself to homeostasis by affecting the Qi flow.

The physiologic effects of acupuncture are being studied and verified by scientific methods. The anatomic locations of acupuncture points coincide with sites of an increased density of nerve endings, small capillary beds and mast cell aggregation. As a result, a measurable physiologic effect in beta-endorphin release, stimulation of circulation and decrease in inflammation results from acupuncture stimulation. In pain control, experiments have shown a modification in neural impulse transmission from the spinal cord to the brain after acupuncture. This effect is known as "gate control" theory, which proposes that acupuncture can block the action of pain fibers in the spinal cord.²⁶

A variety of acupuncture techniques exist. The use of the different techniques depends on the species and general cooperation of the patient, type and severity of the condition being treated, and personal preference of the acupuncturist. Traditional dry needling is commonly used in mammals but is more difficult in birds. Most

juvenile and some adult parrots, columbiformes, water-fowl and poultry readily accept dry needles. The use of 36- or 38-gauge by 15-mm needles is appropriate for parrots, poultry and other larger birds. Plastic Seirin #5 needles can be made lightweight and better balanced by cutting off the plastic handle for better retention of the needle in birds. Smaller birds may require Sooji Chim hand needles (Korean gauge 8-mm length).

An effective alternative to traditional needling is aquapuncture. This technique involves the injection of cyanocobalamin (vitamin B_{12}) or saline into the acupoint using a 27- to 29-gauge hypodermic needle and 0.5- to 1-ml syringe. Medium to large size parrots receive up to 0.10 ml per site, while smaller birds get as little as 0.01 ml per site. The aquapuncture technique has the added advantage of providing a longer lasting effect at the site.

Another technique for potential use in birds is laser therapy. Low-intensity, cold laser lights are effective in penetrating the thin skin of birds to stimulate the shallow acupoints on birds. Disadvantages of laser therapy include the lack of specificity for acupoint stimulation in areas where multiple points are close together and lack of stimulation of deeper acupoints. Gold beads or wire implants have been used in birds for chronic cases requiring much longer periods of stimulation. Acupuncture techniques seldom used in pet birds include electroacupuncture and moxibustion, since birds are Yang by nature and both of these are strong Yang-stimulating techniques.²⁴

The clinical applications of veterinary acupuncture include everything from pain management to treatment of systemic diseases. Acupuncture is effective for many chronic disorders such as allergies, arthritis, urinary incontinence and reproductive disorders. Typically, acupuncture is combined with Chinese herbs and proper nutrition to achieve the greatest effect.

Acupuncture and Traditional Chinese Veterinary Medicine (TCVM) have been developing over the past 20 years in pet bird medicine. Historically, the use of acupuncture on birds in China was primarily restricted to poultry, which was fairly limited due to the lack of economic benefit in treatment of individual birds. Rather, the administration of herbal treatments was more common for flock treatment. However, the use of acupuncture in pet birds has gained some popularity in the USA in recent years, especially for the treatment of feather picking. Despite the lack of historical documentation, acupuncture can be beneficial in the treatment of many pet bird conditions.

The use of acupuncture in birds poses various challenges from their anatomic differences and physiologic

characteristics. Birds have a high metabolic rate and relatively high body temperature (42.4° C) with rapid heart and respiratory rates. They have hollow bodies with air sacs, pneumatic bones and hollow feather shafts. As compared to mammals, birds are relatively dry, possessing minimal moisturizing glands. These characteristics make birds Yang by nature.²⁴ As a result, birds have a tendency toward a relative or true Yang excess when they are sick. The stress and anxiety inherent in the restraint of birds also must be considered when using acupuncture. In addition, because birds instinctively mask signs of disease, they must be thoroughly examined to reveal their true status prior to selection of the acupuncture points.

Acupuncture points are commonly extrapolated from one species to another, and special points are commonly described for individual species. Avian acupuncture employs the same techniques to locate and describe acupuncture points. Transpositional points from mammals constitute the majority of the acupoints in birds, and these may be of TCM origin or special points defined in other species. Special TCM points for poultry without a mammalian counterpart also are used in pet birds, including Gu Duan (end of thigh), used for drooping wings, and Bei Ji (back of the body spine), which is a grouping of three points used to treat respiratory disease. A few points that have been specifically described for pet birds include some of the back Shu points, which do not correspond to the mammalian counterparts because of the fused synsacrum. Detailed descriptions and indications of specific avian acupoints are defined in the listed references.24

Certain disorders in TCVM are more frequently seen in birds. In general, these include Liver Yin deficiency, Heart Yin deficiency, stagnant Liver Qi, Kidney Yin deficiency, Blood deficiency, Lung Yin deficiency and Lung Dryness. Kidney Essence deficiency is common in cockatiels and budgerigars that have been inbred for generations. External pathologic factors, described as Wind-Damp and Damp-Heat, are common in the Western diagnosis of microbial infections.16

Acupuncture can be effective in the treatment of many conventional Western conditions diagnosed in pet birds. Bacterial infections are commonly diagnosed in birds and are described as Damp-Heat or other pathogenic Heat conditions in TCVM. Conjunctivitis can be treated with local points and specific meridian points for Liver/Kidney Yin deficiency. Sinusitis is often the result of a Wind-Cold or Wind-Heat condition, based on the characteristics of the discharge. Various other TCVM conditions can present with sinusitis as a clinical sign. Identification and specific treatment of underlying fac-

tors is just as important in TCVM as in conventional therapy. Crop stasis is thought of as a problem with the Stomach or Liver meridian. The TCVM diagnosis of egg binding is a Kidney Qi condition. Kidney disease is not treated as directly with TCVM in birds as in mammals because the kidney association point is not available, yielding to the use of various kidney meridian points based on the TCVM diagnosis. Applying the basic concepts of TCVM to establish a diagnosis and treat accordingly is more effective than applying a standard set of procedures to a conventional diagnosis. As a point of reference, Table 10.1 has a list of common acupoints used in the treatment of common conditions in pet birds. In addition, Figs 10.1-10.3 illustrate the position of these points.16

HERBAL THERAPY

The use of specific herbs for medicinal purposes dates back thousands of years. Several herbs are mentioned in the Bible, and archeologists have documented herb use back to prehistoric times. Herbs are used around the world, including Western herbs from North America, Ayurvedic herbs from India and traditional Chinese herbs.

Approximately 25% of our conventional drugs are derived from plants. Conventional drugs typically contain a single active constituent from the plant, whereas herbs provide a broader and more balanced effect on the body through the synergistic actions of the herbal components. Herbs are best prescribed to treat the entire individual and not only the clinical signs. Herbal blends and formulations combine the benefits of multiple herbs, which typically produce a synergistic action while minimizing the potential toxic effects of a single herb. Herbs provide many unique qualities that are very limited in conventional medicine, such as anticancer, antiviral and immunoregulation properties.

Currently, herbal products are not regulated or controlled. Therefore, practitioners and clients must remain cautious in administering a product without evaluating the company and verifying that the active component of the herb or plant actually is in the formulation. Product labels can bear the name of an herb or plant substance as long as some portion of it is present in the formulation, but it does not always imply that the medicinally active constituent is included. Standardized extracts are available for certain herbs through concentrating the active ingredients, resulting in more of a plant drug than an herbal medicine.29 Standardizing alters the physical and energetic nature of the herb. This process also eliminates the synergistic effects of the myriad chemical components in the plant. For some herbs such as milk thistle, standardization is advantageous, since the specific active constituent is clearly known and purified in the process.

Table 10.1 | Acupuncture Points in Birds

Acupoint		Characteristics	Indication / Action
LU-1	Avian Fei Tang	Alarm point for Lung	Acute resp. disease, fever, wing weakness
LU-2	Avian Yi Gen	7 dam point for Long	Cold, fever, tracheitis, ptosis of wing
LU-7	Lie Que	Master point for head & neck	Neck stiffness, resp. disease, weak carpus
LU-9	Tai Yuan	Tonification for LU channel	Regulate Lung Qi, clear Lung & Liver heat
LI-4	He Gu	Master point for face & mouth	Facial swelling, eye pain, egg binding, diarrhea
LI-10	Shou San Li	Tonifies Qi	Abdominal pain, Bi syndrome of wing
LI-11	Qu Chi	He Sea point, tonification point	Pain of elbow, abdominal pain & regurgitation
ST-6	Jian Che	The dea point, formited for point	Facial paresis & swelling, neck pain & stiffness
ST-35	Avian Xi Gai		Inflamed, painful & swollen knee, leg weakness
ST-36	Zu San Li	Master point upper abdomen	Tonifies Qi & Blood, raises Yang, body strength
ST-37	Shang Ju Xu	Lower He-Sea point of LI	Chronic diarrhea & loose stool, remove LI damp
ST-40	Feng Long	Connecting point	Resp. disease, muscle atrophy & weak, mental
ST-41	Avian Gou Qian	Tonification point	Bi syndrome in hock & digits, pharyngitis
SP-6	San Yin Jiao		
		"Three Yin meeting" of leg	Egg binding, cloacal prolapse, leg paralysis/pain
SP-9	Yin Ling Quan	Sea & Water point	Distended abdomen, edema, diarrhea, knee pain
SP-10	Xue Hai	Sea of blood	Blood disorders, urticaria, pain in medial thigh
SP-11	Avian Kua Nei	Blood letting point	Inflammation, swelling or poor mobility in legs
HT-7	Shen Men	"Mind door," source point	Mental disorder, epilepsy, feather picking
SI-3	Hou Xi	Tonification point, opening of GV	Neck rigidity, wing contracture, back problems
BL-11	Avian Xin Shu	Assn. point for Heart	Mental disorders, irritability, epilepsy
BL-12	Avian Fei Shu	Assn. point for Lung	Respiratory disease/infection, fever
BL-13	Avian Wei Shu	Assn. point for Stomach	Crop disease, vomiting/regurg., indigestion
BL-14	Avian Pi Shu	Assn. point for Spleen	Maldigestion, indigestion, diarrhea, vomiting
BL-15	Xiao Chang Shu	Assn. point for Small Intestine	Lower abdominal pain, diarrhea
BL-16	Avian Gan Shu	Assn. point for Liver	Hepatopathy, conjunctivitis, inflamed cloaca
BL-17	Avian Xin Shu	Assn. point for Large Intestine	Pain in lower back, LI & cloacal disorders
BL-40	Avian Xi Wan	Master point of back & legs	Inflammation, pain, & swelling of feet & knee
BL-60	Kun Lun	Expels Wind & clears Heat	Pain in back, shoulder & wing, egg binding
BL-62	Shen Mai	Eliminate interior Wind	Epilepsy, mental confusion, pain in back & legs
KI-1	Avian Jiaodi	Foot base, sedation point	Calms mind, tonifies Yin, remove Yin-heat
KI-3	Tai Xi	Greater stream, source point	Infertility, sore throat, back pain, insomnia
KI-6	Zhao Hai	Nourishes Yin, cools blood,	Calms mind, anxiety, soft-shelled eggs, Yin def.
PC-6	Nei Guan	Inner gate, master chest/lung	Mental disorder, pain, epilepsy, fever
PC-7	Da Ling	Source point, sedation point	Gastric pain, regurgitation, panic, epilepsy
TH-4	Yang Chi	Yang pond, source point	Pain in wing & shoulder, kidney disease
TH-5	Wai Guan	Outer gate, connecting point	Motor problems in wing, behavior problems
TH-10	Tian Jing	Heavenly well	Mood swings, Bi syndrome of wing, damp-heat
TH-23	Avian Yan Jiao	Eye correct	Eye problems, expels wind, pain relief
GB-13	Benshen	Point of Yang Linking Vessel	Emotional problems, epilepsy, calming point
GB-29	Ju Liao	Removes channel obstructions	Pain & paralysis of back & legs
GB-31	Avian Kua Wai	Expels Wind - relieves itching	Inflammation, swelling & difficult leg movement
GB-34	Xi Yang Guan	Relaxes Sinews	Pain & swelling of knee (Bi syndrome)
GV-1	Avian Hou Hai	Regulates GV & CV	Loss of appetite, mental depression, prolapse
GV-2	Avian Wai Gen	Extinguishes interior Wind	Diarrhea, mental depression, cloacal prolapse
GV-12	Avian Bei Ji	TCVM poultry point	All respiratory diseases
GV-13	Avian Bei Ji	Similar to Tao Dao, clear heat	All respiratory diseases
GV-14	Avian Bei Ji	GV, BI, GB & ST meeting point	All respiratory diseases
GV-20	Avian Guan Ji	Meeting point of all Yang channel	Mental stress, depression, cloacal prolapse
GV-24	Shenting Du	Meeting point of GV & ST	Severe anxiety & fear (calms mind)
Ba Feng	Avian Jiao Pan	TCVM poultry bleeding point	Relax Sinew, pain & infection in feet
Gu Duan	Avian Gu Duan	TCVM poultry point	Ptosis of wing (poultry), Bi syndrome of pelvis
30 D0011	/ Widir Co Douil	10 m poomy point	1 10010 of willing (pooliny), bi syllatotile of pervis

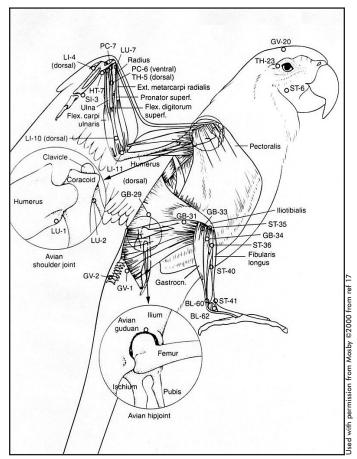

Fig 10.1 | Acupuncture points of birds, lateral view.

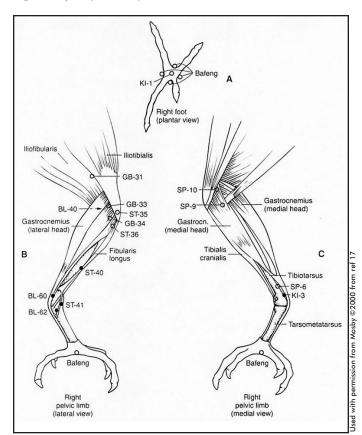

Fig 10.3 | Acupuncture points of the avian leg and foot.

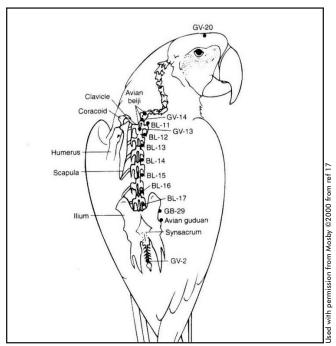

Fig 10.2 | Acupuncture points of birds, dorsal view.

Other factors that affect the potency and medicinally active components of the herb include the method and time of harvest, the parts and preparation of the plant that are included and the handling and processing of the finished product. Only well-known and respected herbal companies should be considered when purchasing herbal products. Whenever possible, fresh herbs or vegetable glycerin-based extracts should be used.

Herbs are effective in the treatment of many conditions in birds. Herbal remedies are much more effective than conventional therapy in treating metabolic conditions such as liver and kidney diseases. Herbs are an excellent alternative to antibiotics in the treatment of infectious diseases, with wider antibacterial effects in addition to various antifungal and antiviral actions. Many of these herbal remedies also support the immune system to assist in the full recovery of the patient. Some herbal formulations serve as detoxification agents, antioxidants and anticancer therapies. Table 10.2 lists several common herbal remedies with potential indications in avian therapy.¹⁸

Liver disease is a common diagnosis in pet birds. Hepatic lipidosis is often the result of poor nutrition, typically sunflower seed-based diets. Other chronic conditions leading to hepatic disease in birds include repeated aflatoxin exposure, heavy metal toxicity and *Chlamydophila* spp. Hepatic fibrosis and cirrhosis are potential sequelae to these conditions. However, conventional therapy falls short in treatment of these liver diseases. Certain herbs have been used for centuries in the treatment of liver disease in people, and these can

Table 10.2 | Herbal Remedies for Birds

Herbal Remedy	Scientific Name	Healing Properties	Indications
Astragalus	Astragalus membranaceous	Immune system booster, especially on the digestive tract	Enteritis and diarrhea, pancreatic disorders, respiratory disease, uric acid excretion
Burdock Root	Arctium lappa	Nutritive liver tonic, blood cleansing, gallbladder stimulant and diuretic	Chronic liver disease, environmental toxins, skin disease and irritation
Chamomile	Matricaria recutita	Analgesic, calming, anti-inflammatory and symptom relief of GI disorders	Calming effects, eg, feather-picking birds
Chaparral	Larrea tridentata	Anticancer, antioxidant, analgesic, antiseptic and anti-arthritic	Cancer treatment with red clover Do not use in egg laying, hand-feeding, or liver-diseased birds
Dandelion	Taraxacum officinale	Potent diuretic (leaf) and increase bile production and excretion (root)	Diuresis - ascites and respiratory fluid, liver disease - increase bile flow
Echinacea	Echinacea	Immune booster (especially against viruses)	Early course of infection, chronic sinusitis viral or candida infections, PBFD support
Elderberry	Sambucus nigra	Anti-inflammatory, alterative and antiviral	Viral infection, viral skin disorders, acute rhinitis and sinusitis
Essiac	Combination of herbs - Indian rhubarb, Slippery elm, Burdock root & Sheepshead sorrel	Anticancer formulation and lessens pain of cancer	Pain, cancer
Feverfew	Tanacetum parthenium	Analgesic and lowers fever	Relieves non-specific pain and inflammation, especially of GI tract
Ginseng	Panax	Potent immune and energy booster (use less than 2 weeks)	Anemia, immune deficiencies, diarrhea, chronic enteritis, cystic ovaries, cancer
Hawthorn Berry	Crataegus	Cardiac supportive, lowers blood pressure	Heart disease, supports heart in several aspects
Marshmallow	Althea officinalis	Antitussive, soothing of membranes and emollient	Cloacaliths and uroliths, mycobacteria, GI inflammation, feather picking
Milk Thistle	Silybum marianum	Hepatoprotective, hepatoregenerative and potent antioxidant	Hepatitis, hepatic lipidosis, cirrhosis, bile duct inflammation, hepatic toxicosis
Mullein	Verbascum thapsus	Emollient, antitussive, antispasmodic, expectorant and vulnerary properties	Self-induced trauma, ear infections, respiratory disorder, diarrhea
Olive Leaf	Olea europaea	Antimicrobial (bacterial, viral and fungal) and diuretic	Virtually any infection (potent effect) ascites - promote fluid excretion
Red Clover	Trifolium pratense	Anticancer, blood cleansing, diuretic, tonic, nutritive, estrogenic	Cancer therapy (with other herbs) supports debilitated patients
St. John's Wort	Hypericum perforatum	Sedative, antidepressive effects, anti-inflammatory and astringent	Pruritic or painful feather picking, chronic viral infection, anxiety
Valerian Root	Valeriana officinalis	Tranquilizer and sedative	Nervousness, convulsions/epilepsy, pain relief, insomnia

be extrapolated for use in birds and other pets. Some of the herbs that support and protect the liver include milk thistle (*Silybum marianum*), dandelion (*Taraxacum officinale*), Oregon grape (*Mahonia* spp.), burdock root (*Arctium lappa*) and licorice root (*Glycyrrhiza glabra*).²⁵

NUTRICEUTICAL SUPPLEMENTS

Nutriceuticals are micronutrients, macronutrients and other nutritional supplements that are used as therapeutic agents. Examples include vitamins and minerals, probiotics, digestive enzymes and antioxidants. This is the clinical application of nutrition in the treatment of disease and metabolic disorders. It is commonly stated that malnutrition is the underlying cause of many of the disease syndromes encountered in birds and exotic pets. Significant advances have been made in avian nutrition with the advent of formulated diets, but it is only the beginning. Specific nutritional requirements have not been established for the various bird species commonly kept as pets, therefore current recommendations and diets are based on anecdotal experience and limited nutritional studies. The primary diet of most pet bird

species should be an organic formulated diet, with limited portions of fresh organic fruit, vegetables and rice. Seeds and nuts should be considered treat items and fed in limited proportions because they are breeding stimulants (see Chapter 4, Nutritional Considerations).

The recommended diet varies according to species, age, health status and activity level. In addition, certain nutritional supplements may be indicated in the face of disease or metabolic challenges to further complement an otherwise balanced diet.

Nutriceuticals are used for various digestive disorders and other metabolic conditions in pet birds. ¹⁸ Some of the commonly used supplements are aloe juice, apple cider vinegar, probiotics and digestive enzymes. *Aloe vera* (Fig 10.4) provides an effective boost to the immune system, a soothing anti-inflammatory effect on the GI tract and is an excellent source of vitamins, minerals and amino acids. Aloe can be administered orally in the form of a gel or juice at the dose of 1 drop per 100 g body weight 3 to 6 times daily or in the drinking water at the rate of 2 ml per 4 ounces of drinking water. Apple cider vinegar is an

Fig 10.4 | Aloe is a hardy plant grown in the full sun. It is often the best source of bioactivity. The gel from inside the plant's leaves is used for wounds. For internal consumption, the pointed edges are removed and the entire leaf is chopped up and offered, or further ground and gavaged.

acidifier of the intestinal tract and entire body. Specific avian indications for apple cider vinegar (organic, nonpasteurized) include chronic bacterial or yeast infections, chronic diarrhea or foul stools and proventricular dilation disease support. It is dosed at 1 to 2 tablespoons per 8 ounces of drinking water, as the only water source for 2 weeks. Probiotics are supplements of beneficial bacteria^a given to reestablish the normal bacterial flora in the digestive tract. They may be administered to birds after antibiotic therapy or severe GI disturbances.

Digestive enzymes are beneficial in birds with pancreatic disease or primary digestive disorders leading to maldigestion. The classic essential enzymes provided in most formulations include protease, lipase and amylase. These may be combined with other specific enzymes or herbs, depending on the condition.

Supplements used in the treatment of inflammatory conditions and arthritis include glucosamine, methyl sulfonal methane (MSM) and proanthocyanidins.18 Proanthocyanidins are a group of strong antioxidants that scavenge destructive free radicals and include grape seed extract, pine bark extract, bilberry and citrus bioflavonoids. These substances provide excellent antioxidant effects that reduce inflammation, improve cellular integrity and eliminate free radicals from the body. Glucosamine sulfate is the preferred and most effective form of glucosamine products. It has reparative effects on arthritis. Some formulations of glucosamine contain chondroitin or MSM for further joint support, but glucosamine is shown to be effective alone. MSM is a sulfur-based supplement that is proposed to have antiinflammatory effects on joints and generally supports healthy tissue and cells. Sulfur is suspected to be an

important mineral for the body to prevent degradation of tissues at the cellular level.

HOMEOPATHY

Homeopathy as practiced today is credited to Dr. Samuel Hahnemann, a German medical doctor from the mid-1800s. The governing principle of homeopathic medicine is "similia similibus curantur" or "like cures like." This concept is based on using a very diluted form of a substance to treat a condition or group of symptoms, which in its full strength would cause the same set of symptoms in the patient. These remedies are made from plants, minerals, drugs, viruses, bacteria or animal substances. Homeopathic remedies work on the deep energetic level of the patient to undermine the constitutional cause of the disease, rather than mask its symptoms.4

Homeopathy is very effective in pet birds. 13 Birds are highly energetic beings and thus are particularly responsive to energetic therapies. In choosing an appropriate homeopathic remedy, the practitioner must be thoroughly acquainted with the Western medical examination, conventional diagnosis, particular behavior characteristics and situational conditions of the avian patient. The mental and emotional disturbances may be difficult to discern, because most bird owners do not fully understand the normal behavior and nature of their pet. Evaluating the bird in its own environment, either personally or by videotape, is invaluable in evaluating these aspects of the diagnosis.

Because most pet birds do not visit the veterinary clinic until they are quite ill, allopathic medications (antibiotics or antifungals) may be required to get the patient through the crisis before treating with the homeopathic remedy. Due to the critical nature of clinically sick birds in practice, the practitioner may not have the opportunity to try a second remedy if the first is ineffective. The first indication of a remedy failure in these cases may be death of the patient. Initial supportive care with allopathic and other holistic therapies to stabilize the critical patient either before or in addition to the homeopathic remedy is recommended by the author.

The practice of homeopathy involves matching the patient's symptoms with an appropriate remedy. The first step involves making a list of the clinical signs from an evaluation and thorough history of the patient. This list is then used to look up rubrics, or lists of potential remedies, for each clinical sign from a homeopathic repertory. The rubrics are compared for overlapping remedies, which are selected as possible treatments. These are then compared in a homeopathic materia medica, which describes all the symptoms potentially treated with that remedy. The remedy that matches the

symptoms or clinical signs most accurately is selected as the first remedy of choice. The most detailed repertories and *materia medica* are based on human symptoms and responses, however, limited veterinary references exist and continue to be developed. An avian homeopathic repertory (Table 10.3) has been compiled¹⁶ and a simplified *materia medica* (Table 10.4) summarized.³ The potency and frequency are selected based on the sever-

ity of the condition and the characteristics of the patient.

Homeopathic remedies are made by serial dilutions of toxic substances that, if used in full strength, would cause symptoms similar to those being treated. Substances are diluted serially, either in 1/10 (X potency) or 1/100 (C potency) stages. Therefore, a 30C potency is a tincture of the homeopathic substance diluted 1/100, 30 times.

Table 10.3 | Avian Homeopathic Repertory

Location	Condition	Treatment					
Beak	Cere, brown hypertrophy	Arnica montana, graphites, lycopodium clavatum, pulsatilla pratensis					
	Easily cracked	Antimonium crudum, natrum muriaticum, silicea					
	Dryness	Silicea, thuja occidentalis					
	Exfoliation	Arsenicum album, graphites					
	Overgrown, distorted	Calcarea carbonica, graphites, silicea, sulphur, thuja occidentalis					
	Chronic liver disease	Argentum nitricum, carbo vegetabilis, chelidonium, calcarea carbonica, graphites, kali carbonicum, lycopodium clavatum, mercurius solubilis, natrum muriaticum, nux vomica, phosphorus, silicea, sulfur, thuja occidentalis					
Extremeties	Arthritis	Amazons - ruta graveolens					
		Budgerigars - bryonia alba, kali iodatum, rhododendron chrysanthum, rhus toxicodendron, sulphur, urtica urens					
		General - aconitum nepellus, arnica montana, belladonna, bryonia alba, ferrum phosphoricum, kali iodatum, ledum palustre, lithium carbonicum, lycopodium clavatum, merdurius solubilis, natrum muriaticum, rhododendron chrysanthum, rhus toxicodendron, ruta graveolens, silicea, sulphur, tuberculinum avium					
		Cold ameliorates - kali sulphuricum, ledum palustre, pulsatilla pratensis, sulphur					
	Broken bones	Symphytum					
		Bruising, associated with - arnica montana					
Feet	Red and ulcerated	Sulphur					
	Paralysis	Argentum nitricum, cocculus indicus, gelsemium sempervirens, hypericum perfoliatum, kali carbonicum, plumbum metallicum					
	Splay-legged	Calcarea carbonica, calcarea fluorica, calcarea phosphorica, fluoricum acidum, gelsemium sempervirens, phosphorus, silicea					
Feathers	Beak and feather disease	Hypericum, sulphur					
	Bronzing of	Arsenicum album, nux vomica, sulphur					
	Growth, none	Arsenicum album, nux vomica, selenium					
	Grooming disorders (plucking or chewing)	Arnica montana, arsenicum album, calcarea carbonica, folliculinum, ignatia amara, natrum muriaticum, nux vomica, phosphoricum acidum, sepia, silicea, sulphur, thallium, tuberculinum avium, veratrum album					
		African Greys - arsenicum album, natrum muriaticum					
		Separation anxiety, with - natrum muriaticum					
		Amazon parrots, in - nux voica, sepia, sulphur, veratrum album					
		Females - aconitum napellus, apis mellifica, calcaria carbonica, chamomilla, lycopodium clavatum, pulsatilla pratensis, silicea, sulphur					
		Males - apis mellifica, camphora officinarum, cantharis, conium maculatum, nux vomica, staphisagria, tuberculinum avium					
	Aggression, general	Nux vomica, tuberculinum avium					
		Cockatoos, in - arnica montana, arsenicum album, chamomilla, ignatia, natrum muriaticum, nux vomica, sepia					
		Males, in - nux vomica					
		Females, in - pulsatilla pratensis, silicea					
		Folliculitis, secondary to - hepar sulphuris, hypericum perforatum, kali bichromicum, mercurius solubilis, sarsaparilla, staphisagria, sulphur					
		Frantic - belladonna, stramonium, veratrum album Macaws, in - nux vomica, tuberculinum avium Males, in - nux vomica Sexual - nux vomica, sepia					
Female	Binding, egg	Calcarea carbonica, kali carbonicum, pulsatillapratensis					
		Blood on eggs, with - pulsatilla pratensis					
		Soft-shelled eggs - calcarea carbonica, kali carbonica					
	Egg laying	Kali carbonica, lycopodium clavatum, pulsatilla pratensis, sepia					
		Soft-shelled eggs - kali carbonica					
		Stopping of - sepia					
	Infertility	Natrum muriaticum, sepia, silicea					
	Ovarian cysts	Arsenicum album, belladonna					
-							

Table 10.3 | Avian Homeopathic Repertory (continued)

Location	Description	Treatment				
	Abscesses, Granulomas	Tuberculinum avium				
Generalines	Anemia	Calcarea carbonicum, ferrum metallicum, plumbum metallicum, sulfur				
	- · · · · · · · · · · · · · · · · · · ·	Acetic acid, carbo vegetabilis, phosphoric acid				
	Transmissia, slow to recever	Ailments from - acetic acid, carbo vegetabilis, hepar sulphurous, phosphorus, phosphoric acid				
	Cancer	Calcarea carbonica, carcinosinum, graphites, lycopodium clavatum, nitricum acidum, phosphorus, silicea, sulphur, thuja occidentalis				
		Budgerigars, in - calcarea carbonica, carcinosinum, graphites, lycopodium				
	Candida albicans infection	Familial history of - carcinosinum, lycopodium clavatum Calcarea carbonica, calcarea phosphorica, china officinalis, helonias dioica, lycopodium clavatum, medor-				
		rhinum, pulsatilla pratensis, natrum phosphoricum, nitricum acidum, sepia, thuja occidentalis				
	Emaciation	Arsenicum album, calcaria carbonica, calcaria phosphorica, iodium, natrum muriaticum, nux vomica, lycopodium clavatum, pulsatilla pratensis, phosphorus, sepia, silicea, sulphur, tuberculinum bovinum				
		Appetite ravenous with - baryta carbonica, baryta iodata, calcaria carbonica, calcaria phosphorica, causticum hahnemanni, china officinalis, cina, iodium, lycopodium clavatum, natrum muriaticum, nux vomica, silicea, sulphur				
	Exposure to tobacco smoke, ailments	Gelsemium sempervirens, nux vomica, tabacum				
	Lead poisoning	Alum, aurum metallicum, causticum, lycopodium clavatum, mercurius solubilis				
	Pyemia	Arsenicum album, calcaria carbonica, hippozaenium, lachesis, pyrogenium				
	Sepsis	Arsenicum album, arsenicum iodatum, baptisia tinctoria, china officinalis, crotalus horidus, echinacea angustifolia, lachesis				
	Trauma	Aconium napellus, arnica montana, hepar sulphuris calcareum, rhus toxocodendron, ruta graveolens, symphytum officinale				
		Head, with seizures - belladonna				
		Neurologic symptoms, with - hypericum perforatum				
	Vaccinations, acute reactions	Aconitum napellus, apis mellifica, belladonna, thuja occidentalis				
		Ailments after - aconitum napellus, apis mellifica, belladonna, mercurius solubilis, phosphorus, silicea, sulphur, thuja occidentalis				
	Weakness, unable to rise due to severe illness	Carbo vegetabilis				
	Zinc poisoning	Aurum metallicum, mercurius solubilis				
Heart	Cardiomyopathy	Crataegus oxyacantha et monogyna, digitalis purpurea				
	Cyanosis	Digitalis purpurea				
	Heart, general	Crataegus oxyacantha et monogyna, digitalis purpurea, rhus toxocodendron				
Liver	Liver disease, general	Nux vomica, lycopodium clavatum, phosphorus				
	Fatty liver disease	Calcaria carbonica, carbo vegetabilis, chelidonium majus, kali bichromica, kali carbonica, lyssinum (hydrophobinum), lycopodium clavatum, mercurius solubilis, nux vomica, phosphorus, picricum acidum, sulphur				
Mind	Agitated, overstimulated	Lachesis, stramonium, veratrum album				
		Outlet, without - ignatia amara, lachesis, nux vomica				
	Aggression	Nux vomica, pulsatilla pratensis				
	Anger	Arsenicum album, chamomilla, ignatia amara, lycopodium clavatum, nitricum acidum, nux vomica				
		Underlying - nux vomica				
		Violent - aconitum napellus, lycopodium clavatum, nitricum acidum, pulsatilla pratensis				
	Anxiety	Aconitum napellus, argentum nitricum, arsenicum album, belladonna, calcaria carbonica, calcaria phosphorica, cannabis indica, carboneum vegetabilis, conium maculatum, euphasia officinalis, hyoscyamus niger, ignatia amara, kali carbonicum, kali nitricum, lachesis, lycopodium clavatum, mercurius solubilis, natrum muriaticum, nitricum acidum, phosphorus, pulsatilla pratensis, sepia, silicia, sulphur, thuja occidentalis, veratrum album				
	Cowardliness	Gelsemium sempervirens, lycopodium clavatum				
	Dependent on others	Baryta carbonica, pulsatilla pratensis				
	Fatigue, mental, from inability to adapt to new surroundings	Conium maculatum, kali phosphoricum, picricum acidum				
	Fear, violently throwing self around cage	Aconitum napellus, belladonna, lycopodium clavatum, nux vomica, stramonium, veratrum album				
	Grief	Causticum hahnemanni, natrum muriaticum				
	Irritability	Kali sulphuricum, natrum muriaticum, nitricum acidum, nux vomica, phosphorus, sepia				
		Idle, while - calcarea carbonica				
	Jealous, bites owner when others approach	Calcarea sulphuricum, hyoscyamus niger, lachesis, lycopodium clavatum, nux vomica, pulsatilla pratensis, stramonium				
	Rigid, unable to adapt to captivity	Calcarea carbonicum, kali carbonicum				
	Sensitivity	Gelsemium sempervirens, natrum muriaticum, pulsatilla pratensis, silicia				
	Timid	Kali sulphuricum, pulsatilla pratensis				

Table 10.3 | Avian Homeopathic Repertory (continued)

Location	Description	Condition				
Mouth	Pharynx	Inflamed, chronic - graphites, sulphur				
		Choanae, elongated - phosphorus				
		Choanal papillae, eroded - phosphorus				
Nerves	Ataxia	Arsenicum album, calcaria carbonica, nux vomica, phosphorus, plumbum metallicum, silicea, stramonium, zinc				
	Nerves, general	Rhus toxicodendron, hypericum perforatum				
	Paralysis	Argentum nitricum, cocculus indicus, gelsemium sempervirens, hypericum perforatum, kali carbonicum, lachesis, phosphorus, plumbum metallicum, zinc				
		Renal tumors, with - hypericum perforatum, lycopodium clavatum				
	Seizures	Aconitum napellus, belladonna, calcaria carbonica, ignatia amara, lycopodium clavatum, silicia				
		Status epilepticus - aconitum napellus, belladonna				
	Weakness	lodium, nux vomica, plumbum metallicum, silicea, zinc, zinc phosphoricum				
Nose	Catarrh	Graphites				
	Colds, get easily	Graphites				
	Coryza	Graphites				
		Dry, obstructed - phosphorus				
	Pharyngitis	Nux vomica, phosphorus, sulphur				
	Sinusitis	Arsenicum album, bryonia alba, hepar sulphuris, calcareum, kali bichromicum, kali nitricum, lycopodium clavatum, mercurius solubilis, natrum muriaticum, nux vomica, phosphorus, pulsatilla pratensis, silicea				
Pediatrics	Infantile behavior	Baryta carbonica				
	Separation anxiety	Nux vomica				
	Slow development	Calcaria carbonica				
	Stunted growth, in chicks	Baryta carbonica				
Respiratory	Chronic colds	Graphites				
	Chronic upper respiratory infection	Arsenicum album, graphites, sulphur				

Table 10.4 | Avian Homeopathic Materia Medica

Materia	Indication	Usage Comments			
Acetic acid (glacial)	Antidote for vaporized anesthetics.	It can liquefy catarrh, which causes desperate gasping for breath. Antidotes include aconite, ignatia and opium. It must be neutralized before use of other medications - aconite is the ant dotes for it. Not compatible with Arnica, Lachesis, Mercuris and Causticum.			
Aconitum napellus (monkshood)	For effects of shock from injury, with fear; physical and mental restlessness.	First aid for skin injuries from cat scratches and tears, inflammation. Diarrhea during very hot weather. Useful where there is redness of skin and bird is very restless and frightened State of collapse, where heat and fear are present.			
Alumen (common potash alum)	Useful in cases of diarrhea, especially when bird is eating well and will not cease eating to produce a dropping.	Antidote for lead poisoning and other mercurials.			
Apis Mellifica (honey bee)	Most cases of swelling, especially from bee stings.	Useful in cases of reddened eyes with surrounding swelling.			
Argentum nitricum (nitrate of silver)	Loss of balance and coordination of mind and body.	Trembling in affected parts. Legs are withered, bird agitated. Ocular ulcers and abundant discharge.			
Arnica (leopard's bane)	First aid for any injuries from blows, with bruising or danger of concussion.	Use for concussion. Sprains or strains respond well. Useful before and after surgery. For broken skin with bruising, do not apply directly to wound, but dose internally. Okay to use as ointment to bruises if skin is intact. Causes of diarrhea caused by accident or shock from surgery respond well. Useful for problems caused by old injuries. Aconite is complementary.			
Arsenicum album (arsenic trioxide)	Bird is restless and prepared to bite. Body temperature is normal and eyes bright.	Useful in cases of food poisoning, often caused by bad meat; usually with green-stained vent feathers. For red, swollen legs, but not as puffy as for Apis. Gradual weight loss from impaired nutrition. Ill effects from fright. Paralysis with atrophy of legs. Putrid odor from discharges. Ailments during varying weather conditions.			
Aurum metallum (gold)	Cases where bird is quiet and ready to give up and die. Sometimes is glassy eyed.	Knees weak, worse in cold weather; usually remedy for winter complaints. Antidote for lead poisoning.			

Table 10.4 | Avian Homeopathic *Materia Medica* (continued)

Materia	Indication	Usage and Comments
Belladonna (deadly nightshade)	Bird is restless, unnaturally glaring eyes; convulsive movements; aversion to water; changeable attitudes. It attacks one moment and hides the next.	Useful for swollen joints; tottering gait. Cold legs and feet with jerking limbs. Wants to stand up and will not lie down.
Bellis perennis (daisy)	Use for results of accidents with nerve injuries.	Lameness from strains and sprains; sore joints and muscular stiffness. First remedy in injuries to deeper tissues and after major surgery.
Calcarea carbonica ostrearum (carbonate of lime)	Useful for abscesses in deep muscles.	For relapses during convalescence. Helps blood to clot. Eyes sensitive to light. Bird hides head in corner. Swollen eyelids. Extreme difficulty in breathing.
Calcarea Suphurica (plaster of paris)	Follows Ruta well in cases of leg stiffness.	Useful for inflammation with thick yellow discharge. Diarrhea with blood.
Calendula officinalis (marigold)	Great healer of wounds.	Stops bleeding and aids in formation of healthy tissue. Applied topically as tincture or cream or taken internally as tablet. Useful for lacerations.
Carbo vegetabilis (vegetable charcoal)	Bird is usually slow, quiet and cold. Eyes partially closed.	Used for food poisoning caused by fish.
Dulcamara (bittersweet)	Ailments caused by damp.	Recurrent rheumatism during wet weather. Birds that look ill during cold, wet weather, but no specific cause. Stiff legs; drooping wings; any weakness; chills - during wet weather.
Euphrasia (eyebright)	Use for red, sore eyes; ocular discharge.	
Gelsemium (yellow jasmine)	Bird is tired; weakness or paralysis; chilliness.	No fear of handling, and fatigued after slightest movement. Negative response to fear or fright.
Hamamelis virginica (witch hazel)	Stops bleeding.	ldeal after surgery - superior to morphine for pain. Great value in open, painful wounds. Bruised soreness of affected parts.
Hepar sulphuris calcareum (Hahnemann's calcium sulphide)	Use for suppuration with pain; unhealthy skin.	Use on sensitive ulcers and abscesses that bleed easily.
Hypercal	Useful for wounds.	Cleansing, healing and pain removing.
Hypericum (St. John's wort)	Useful for injuries involving nerves, especially toes and claws.	Injured nerves after predator attack. Relieves pain after surgery. Paralysis of legs due to mechanical spinal injury (higher potency).
Ignatia (St. Ignatius' bean)	For grief and loss of mate. For fear.	Very nervous birds; ideal for female birds that are quick, but submissive. Rapid characteristic change from quiet to panic. Fluctuating signs between appearing ill and healthy. Useful for injuries of the spine.
Ipecacuanha (ipecac root)	For upset stomach, where bird is hot.	Respiratory trouble; congestion in chest or throat; gasping for breath. General weakness of body, eyes partially closed.
Lachesis (bushmaster)	Dirty and infected wounds; sepsis; risk of gangrene.	Dark appearance of wounds.
Lathyrus (chick pea)	Paralysis without pain.	Legs dangle when picked up. Cold limbs. Slow recovery of nerve function. Cannot lift feet off ground, yet cannot lower hocks to ground.
Ledum (marsh tea)	Use for puncture wounds, especially if wound is cold.	Useful as antitetanus. Bottom of feet painful, reluctant to stand on them.
Lycopodium (club moss)	Ailments that develop slowly.	Functional powers weakening with failure of digestive function, with liver disturbance.
Manganum aceticum (manganese acetate)	Progressive paralysis with wasting of limbs.	Feeble and staggering gait; leans forward while walking, so falls onto beak. Swelling of joints; sore feet. Worse in cold weather.
Mercurius hydrargyrum (quick silver)	Indicated in weight loss; feather loss; tremors, great prostration; sensitivity to heat.	Ulceration of mouth and throat; abscesses; foul-smelling excretions; tendency for pus formation, usually greenish, thin and streaked with blood. Antidote for mercury poisoning.
Natrum muriatum (chloride of sodium)	Indicated for weakness and weariness.	Ill effects of fright. Easily irritable. Complements Ignatia.
Opium-papaver somniferum (dried latex of poppy)	Drowsy stupor. Painfulness. Lack of reaction to stimuli. Warm to hot bodied.	Does not respond to indicated remedies. Birds tuck their heads under their wings and refuse to wake up, poorly responsive.
Oxalicum acidum (sorrel acid - oxalic acid)	For short, jerky breathing, with constriction.	Paralysis due to spinal injury.
Petrolrum (crude rock oil)	Antidate for oil pollution, especially oiled birds that have digested oil off feathers.	
Plumbum metallicum (lead)	Lead poisoning, especially paralysis of wing.	Progressive muscle atrophy, excessive and rapid emaciation. Anemia. Do not give many doses of this remedy.

Table 10.4 | Avian Homeopathic Materia Medica (continued)

Materia	Indication	Usage and Comments
Phosphoricum acidum (phosphoric acid)	Loss of vital fluids, after diarrhea or blood loss.	Listlessness. Dyspnea. Effects of shock; gives up on life.
Psorinum (scabies vesicle)	Bird is cold and poor response to indicated remedy.	Foul odor to secretions. Single dose of 30C or 200C usually sufficient, followed by indicated remedy.
Pulsatilla (artificial sepsin - pyrogen)	Usually indicated in female changeable in characteristics.	Signs improve when outside; little to no thirst; worse from heat. Limbs are painful; stiffness in legs; swollen veins in wings; red, inflamed and swollen feet. Bird wants to sit or lie down.
Pyrogenium (artificial sepsin - pyrogen)	Food poisoning, with offensive brown-black diarrhea.	Offensive discharge; pain and burning in affected areas. Patient is restless. Great antiseptic.
Rhus Toxicodendrom (poison ivy)	Rheumatic pains are worse when limbs are kept still; bird stiff until it gets moving.	Ailments from strains; getting wet while hot. Rheumatism in cold weather. Limbs stiff, paralyzed; hot, painful swelling of joints. Worse in cold air.
Ruta graveolens (rue bitter wort)	Strained limbs, usually after Arnica stops working.	Ideal for stiff legs and/or wings.
Silicea (silica pure flint)	Promotes suppuration; brings abscesses to a "head."	Bird is cold and tired. Slow recovery after respiratory problems. Loss of strength in legs; bottom of feet are sore.
Scirrhinum	Specific for cancer.	Use with care.
Sulphur (sublimated sulphur)	Used with Aconite in cases of collapse where Aconite is indicated.	Used with Ipecac in cases of collapse. Complaints that relapse. Birds are lazy, but snappy; thin and weak; good appetite. Helps paralyzed legs after use of Rhus tox.
Symphytum (comfrey)	Healing of broken bones, tendons and sinews.	Increases strength and rate of healing. Helps heal injured eyes.
Urtica urens (stinging nettle)	For burns and scalds.	Used in tincture, cream or tablet.
Zincum Metallicum (zinc)	Lameness and weakness with twitching of various muscles.	Sensitive to noise; lethargic; cold feet. Works well with Manganese acetate.

Succession is carried out at each stage to release the curative energy of the substance to imprint on the memory of the water at the energetic level as well as remove the toxic and harmful effects of the substance. The end result is a homeopathic substance that contains only the energetic signature of the toxic substance, but no physical amount of the substance itself.

FLOWER ESSENCE THERAPY

Healing with flower essences proposes similar principles to homeopathy. Both forms of therapy are based on curing the patient by restoring the body's energy pattern and vibrational characteristics. The underlying premise is that all life forms possess an innate vibrational energy force that is disrupted by conditions and circumstances of our environment, leading to disease and illness.⁸ These disruptions are further related to emotional and behavioral specifics, which can be characterized and treated with the vital energy or essence of certain flowers. The aroma or essence of a flower naturally elicits an emotional response, similar to the way music affects an individual's mood.

Dr. Edward Bach is credited for the development of the first 100-year-old therapeutic system of flower essence therapy.² Dr. Bach was a distinguished British physician in the early 1900s with a strong influence from Hahnemann

and the concepts of homeopathy. Dr. Bach developed various vaccines during his tenure in immunology, and then developed some of the first nosodes, oral homeopathic vaccines. In his clinical experience, Dr. Bach realized the importance of the mental and emotional states of mind in the recovery from illness. In 1930, he embarked on a quest to develop a treatment method that did not depend on the destruction or alteration of one living thing to benefit another, which ultimately lead to the discovery of his first twelve healing herbs with a natural affinity to mental traits. In all, 38 healing remedies were identified, which he believed would remedy all the negative states of mind that afflict mankind.

A variety of other flower essences have been described in the past 30 years. In the 1970s, Richard Katz and Patricia Kaminski developed the California Flower Essences. Ian White described the Australian bush flower essences in the 1980s, influenced by the Australian Aborigines' traditional knowledge and experience with native plants. Other flower essence lines include the Alaskan (1980s), Bailey in Britain and Celestial Remedies (1990s), to name a few.⁸ All of these flower essence lines are based on the same premises described by Dr. Bach.

Flower essences can be very effective in the treatment of clinical and behavioral issues of birds and other pets. The underlying premise in using flower essences to treat conditions in birds is the presence of an emotional component to the problem. These formulations act on the energetic signature of different emotions that produce the outward behaviors. It is commonly accepted that emotional and psychological stress can lead to physical illness; therefore, the flower essences can be incorporated into a holistic treatment plan.

In general, birds are more emotional than most other animals.2 The stress and anxiety experienced by birds during treatment may be more detrimental than the disease condition itself; therefore, the use of a flower essence prior to and during a veterinary exam and treatment may significantly improve the chances of survival. Birds also respond quickly to the remedies, probably due to their sensitive emotional natures. Most formulations of flower essence are based in brandy, which can be harmful to the patient if given directly. Therefore, these remedies should be diluted in spring water before they are administered to birds at the rate of 10 to 12 drops per ounce of water.

Birds present with a number of medical conditions that have an emotional or behavioral basis. Feather picking is by far the most common and frustrating of these conditions. A more progressive and intense manifestation is self-mutilation, as exhibited in Moluccan cockatoos chewing into the pectoral muscles of their chests. Biting and screaming are other undesirable behaviors that are merely displaced natural behaviors, which can be modified with flower essence remedies. Birds that suffer from a physical loss of a companion, physical injury or medical illness can be supported with these remedies as part of their therapy.

The choice of remedies is individualized for each patient. Oversimplification by using a single remedy for a particular problem is much less effective than thoroughly evaluating the patient and formulating a remedy of various flower essences. Of course, there are certain remedies^a that are commonly effective for a particular condition such as the stress and anxiety of a veterinary visit or treatment. Rescue Remedy is a classical formulation of five flower remedies, consisting of star-of-Bethlehem, rockrose, impatiens, cherry plum and clematis. This remedy can be sprayed in the exam room, sprayed directly onto the bird or given directly by mouth.¹⁵ A list of the classic Bach Flower Essences and their basic uses is summarized in Table 10.5.28 Extensive repertories of other flower essences exist for man11 and animals.5

AROMATHERAPY

The therapeutic application of aromatic essential oils is known as aromatherapy. The administration of the oils by diffusion or aerosolization is most common, but topical and oral applications also are effective routes for some formulations. The essential oils act on the underlying

vibrational energy of the patient to restore the energetic imbalance causing the disease or condition. By increasing the vital force of the patient, aromatherapy strengthens the natural immune system and promotes self-healing.9

Birds are extremely susceptible to any aerosolized agents, including essential oils used in aromatherapy. Therefore, care must be taken not to overwhelm the bird's respiratory system with too strong a treatment. An electric aromatic diffuser can be used in a well-ventilated room for 5-minute intervals, several times daily for certain conditions. The scent of the essential oils should be barely detectable, or else it is too strong for the bird's respiratory system. Some aromatic agents may inherently be too strong or noxious for use around birds, therefore, these should be used with caution. This therapy is used less commonly in birds, except for cases of stress reduction, due to the potential respiratory risks.

Some conditions in pet birds respond well to aromatherapy, including certain respiratory ailments and stress and anxiety issues. A respiratory essential oil blend for diffusion consists of eucalyptus (50%), pine (25%), tea tree (10%), and niaouli or cajeput (15%). This blend is diffused near the cage several times daily for 5-minute intervals. A 15-ml essential oil blend for stress and anxiety is composed of lavender (10 ml), marjoram (4 ml) and neroli (1 ml).9 This is diffused for 5 minutes near the cage, repeated 4 to 5 times daily. A diffusion of lavender, bergamot or ylang ylang in the exam room provides a calming and relaxing effect on the patient, client and doctor.23 The electric aromatic diffuser can be turned on in the waiting room or exam room for 5 to 10 minutes every 3 to 4 hours during the day.

ENERGY THERAPY

Various forms of energy therapies have developed through the ages in many cultures. Some of the currently practiced energy therapies include Reiki, therapeutic touch and pranic healing. These healing practices involve directing the ability to consciously modulate the energies of a living being. These healing practices involve the healer or practitioner serving as a conduit for the universal energy to stabilize or balance the patient's innate energy field.

Therapeutic touch is an example of this type of therapy that is practiced throughout the world. Dolores Krieger and Dora Kunz developed this practice based on the following four basic scientific premises:12 1) Humans and animals are physically open energy systems. This implies that the transfer of energy between living things is a natural and continuous process; 2) Humans and animals are bilaterally symmetrical, implying a pattern to the underlying energy field; 3) Illness is an imbalance in an individual's

energy field, with healing being achieved by balancing this energy field; and 4) Humans have natural abilities to transform and transcend their conditions of living. Other forms of energy therapy and healing arts are based on similar assumptions and current scientific premises.

Therapeutic touch and other energy therapies produce certain consistent and reliable results. The first response experienced within a few minutes of a treatment is relaxation. Clinically, there is a significant reduction or elimination of pain. Healing responses tend to be accelerated, presumably by boosting the patient's immune system. Psychosomatic illnesses are alleviated through the effects on the patient's autonomic nervous system.

The success of these therapies is based on the learned skills and techniques combined with intentionality. Proper centering and focus is critical in assessing the patient's energy field for subtle changes and asymmetry. With practice and deliberate intent, the healing practitioner can balance the patient's energy. This technique is very useful in calming and soothing nervous or distressed patients; it also helps ease the induction and recovery from anesthesia. The pain and discomfort from trauma or illness, as well as boosting the body's innate healing response, can be relieved through this energy modulation.

Integrative Therapies for Common Avian Conditions

FEATHER PICKING

Feather picking is a clinical sign of a multitude of potential diseases and disorders and not a diagnosis in itself. The underlying causes include systemic or metabolic disorders (see Chapter 4, Nutritional Considerations, Section II Nutritional Disorders), infectious diseases, allergies, parasites and psychogenic disturbances. Most cases are psychogenic in nature, but they should have a complete diagnostic analysis to rule out other contributing factors. Treatments for feather-picking disorders vary considerably but should be based on the individual assessment with an attempt to address the underlying factors as well as the psychogenic manifestations.

Many integrative therapies can be utilized to complement the conventional approach to treating a feather-picking bird. Some of these address the psychogenic component of the problem, including Bach flower essences, herbal therapy and aromatherapy. Other modalities address the deeper energetic components, such as acupuncture and homeopathy. Some treatments are directed at stabilizing the nutritional or metabolic imbalances, such as nutriceuticals and antioxidant therapy.

Acupuncture is reported as a viable option for the treatment of feather picking in pet birds.^{1,7,16,24,28} The conventional diagnosis of feather picking is often attributed to the social/emotional well-being, psychological status or stressful environmental conditions of the bird. This

determination relates to a TCVM diagnosis as a Shen disturbance (deficient Heart Blood), Phlegm and Heat disturbance of the Heart, Heat invading the Pericardium, or excess Liver Yang.28 Certain acupuncture points are routinely used in birds with feather-picking issues, but the final selection of points should be based on a complete assessment of the patient and TCVM diagnosis. Some of the routine points include SP-6, ST-36, LI-4, LI-11, PC-6 and HT-7. SP-6 is used to tonify and strengthen Yin. ST-36 is the master point of the abdomen and used to treat deficiencies, dispel Cold and tonify Qi and Blood. LI-4 helps to expel Wind Heat and to release the Exterior, tonify defensive Qi and calm the spirit. LI-11 is used to clear Heat, resolve Dampness, and regulate Nutritive Qi and Blood. PC-6 can calm the mind, regulate Heart Qi and relieve irritability due to stagnation of Liver Qi. HT-7 is useful in calming the mind, quieting the spirit, improving thinking and regulating other emotional issues. Other potential points used for feather-picking cases include GV-20, LIV-3, GB-34, SP-10, SP-11, BL-12 and BL-15. Table 10.1 lists the common avian acupuncture points and general indications for use. The treatment regimen is dependent on each case but is usually started at once to twice weekly for the first several weeks and gradually reduced, based on the patient's response. Each session should begin with an assessment of the patient's condition and response, with adjustment of the selected acupuncture points as indicated.

Homeopathy is useful at addressing the underlying energetics of the feather-grooming problem but must be individualized for each patient. 19 A homeopathic remedy is prescribed based on the full assessment of the patient; however, certain remedies commonly surface as primary choices. Some of these include aconitum napellus, apis mellifica, arnica montana, arsenica album, belladonna, ignatia, natrum muriaticum, nux vomica, pulsatilla pratensis, psorinum, sepia, staphisagria, stramonium, tuberculinum avium and veratrum album.19 An avian homeopathic repertory has been summarized in Table 10.3. In general, the study of homeopathic remedies for mental problems will reveal the proper remedy. Each type of bird has general personality characteristics that can influence the choice of remedy. For instance, cockatoos are very social birds, thus requiring a remedy that addresses social issues when separated from the flock. Alternately, Amazon parrots and macaws are more likely to be suffering from internal systemic diseases, requiring a remedy to address those problems as well. The homeopathic remedy, potency or frequency may have to be adjusted based on the patient's response and discontinued upon resolution of the problem.

Western herbs are helpful in treating the psychological issues and calming the feather-picking patient.¹⁹ Saint

John's wort has many properties that make it particularly useful in the treatment of feather picking. Numerous scientific studies have determined that Saint John's wort is an effective antidepressant.²⁹ In addition, it serves as a nerve tonic and speeds wound healing, which is useful in soothing and repairing the damaged feather follicles. Saint John's wort has good antibacterial and antiviral properties, beneficial in cases of infectious folliculitis or systemic diseases. Several other herbs are sedative and soothing in nature, including valerian root, passion-flower and kava kava.²⁹ These may be effective individually or in combination for the management of very nervous and hyperactive patients.

Bach Flower Essence is excellent at addressing the underlying emotional and behavioral issues that often serve as the root of the feather-picking condition.^{8,19} A combination of three to five different essences may be indicated for an individual case. Some essences address the underlying issue of fear or anxiety, such as aspen, agrimony, cherry plum, mimulus and rockrose. Others are useful when birds are picking at certain times or situations, such as red chestnut or heather for when the bird picks when left alone or scleranthus for when picking occurs during breeding season. Mustard or gorse may be indicated if the bird is feather picking out of depression. Walnut is helpful when feather picking begins after a move or other change in the environment. Wild oat can be given if the bird is simply over-preening, while agrimony is a better choice for self-mutilation. Chicory is a good choice when the picking is used to get attention, whereas cherry plum is used when the picking seems to be compulsive in nature. Most flower essence formulas also should contain a combination remedy^b of impatiens, clematis, rockrose, cherry plum and star-of-Bethlehem for stress and anxiety. This formula also is used to calm patients for veterinary examinations, aid in recovery after surgery and treat shock and distress during severe illness or injury. Table 10.5 contains a summary of the flower essences and general indications.

A variety of nutriceuticals can be added to balance the nutritional deficiencies and resolve underlying metabolic conditions leading to feather picking. 1.19 Aloe vera has anti-inflammatory and vulnerary effects, which assist healing of damaged and irritated skin and feather follicles in feather-picking cases. Aloe also provides a multitude of nutrients for healthy feather condition, including natural vitamins, minerals and amino acids. Antioxidants are often beneficial in treating chronic feather-picking cases by scavenging free radicals and supporting the healing process of damaged skin and feathers. Potent antioxidants, also called oligomeric proanthocyanidins, include grape seed extract, pycnogenol, bilberry and citrus bioflavonoids. These are available in various forms, either individually or

in combination, and can be added to the food or water as a general supplement. A potent amino acid supplement, 5-hydroxy L-tryptophan, has been suggested for feather-grooming problems. ¹⁹ Being very potent, only a few grains should be added to the food daily. Omega-3 fatty acids have been suggested for a variety of veterinary conditions including feather disorders. The benefits of omega-3 fatty acids pertinent to feather-picking disorders include treatment of seborrhea and pruritus as well as mood stabilization. ¹ These fatty acid supplements also help reduce inflammation by modifying the arachidonic acid cascade.

DIGESTIVE DISORDERS

The digestive tract of birds is often disrupted by infectious and metabolic conditions. This can include anything from sour crop caused by *Candida albicans* to cloacal papillomas. Whenever possible, the underlying cause of the gastrointestinal (GI) disorder also must be identified and rectified. Many of these disturbances, however, can be stabilized with the use of nutriceuticals and herbal formulations. Several aspects of the digestive process can be addressed with these supplements, including soothing and protecting the GI mucosa, balancing the microbial population and providing nutritive support.

The GI mucosa is easily inflamed and irritated by invading pathogens or foreign agents. As a result, the inflamed mucosa will be less effective in the absorption of nutrients and proper digestion. Several Western herbs are highly effective in soothing the inflamed GI mucosa.²⁹ Slippery elm bark has a soothing, protecting and lubricating effect on the GI tract. In addition, it serves as an astringent and nutritive. The tannin constituents tighten the digestive mucosa to relieve inflammation and prevent further fluid loss in the intestines. The mucilage constituents help lubricate the digestive tract and facilitate the removal of waste material. Slippery elm is effective in many digestive conditions on several levels. Marshmallow root provides a soothing, lubricating and protective barrier to mucosal surfaces through its mucilage component. This makes marshmallow beneficial in cases of GI ulceration or irritation. Marshmallow is best taken internally as a tea or low-alcohol tincture. Licorice root is an excellent anti-inflammatory and demulcent herb. It is good at healing GI ulcerations and reducing the gastric acid secretions while producing anti-inflammatory effects similar to corticosteroids.

Several nutriceutical products have beneficial nutritive and supportive effects on the digestive tract. *Aloe vera* is an excellent nutritive and anti-inflammatory agent. *Aloe vera* is effective in treating inflammatory bowel disorders and constipation. The active constituents of *Aloe vera* include barbaloin and isobarbaloin. Aloe has purga-

tive, cholagogue, anti-inflammatory, vulnerary and anthelmintic effects on the GI tract.14 Aloe vera juice can be dosed orally at 1 to 2 drops per 100 g body weight or added to the drinking water at the rate of 2 ml per 4 ounces of drinking water. Apple cider vinegar is an excellent acidifier to the intestinal tract and general nutritive.19 Indications for use include chronic diarrhea, dysbiosis, candidiasis and chronic bacterial enteritis. Apple cider vinegar can be added to the drinking water at the rate of 1 to 2 tablespoons per 8 ounces of water for up to 2 weeks. A line of rice-based intestinal support products^c is commercially available. Rice is highly digestible and gluten free, thereby being a good hypoallergenic whole-grain product. Certain protein fractions of rice support gastrointestinal secretory function and repair of mucosal cells.¹⁴ Therefore, these rice-based products are well suited for management of gastrointestinal inflammatory and allergy disorders, including chronic vomiting, chronic diarrhea, dysbiosis, food allergy and gram-negative enteritis. One rice-based product, Ultraclear^c, is dosed at 1 g per kg body weight, given 3 times daily.

The digestive system of birds has evolved with plant enzymes for proper digestion. As more cooked and processed foods are fed to pet birds, fewer digestive enzymes are found in the diet because cooking inactivates the plant enzymes. Animal source digestive enzymes, such as pancreatic enzymes, are less effective in birds, because they are inactive in acidic environments such as the bird's crop and proventriculus. Therefore, pet birds should be provided plant sources of digestive enzymes, which are stable and active over a wide pH range. A source of natural enzymes produced by *Saccharomyces cerevisiae* in fermentation vats has empirically shown to have beneficial effects in birds (G.J. Harrison, personal communication, 2003).

A wide variety of digestive disorders in birds, including bulky stools, intestinal gas, undigested food in feces, slow crop emptying, chronic bacterial enteritis, weight loss and chronic immunosuppression, benefit from the addition of digestive enzymes.

Probiotics are microbial supplements given to reestablish a balanced gastrointestinal microflora. These products generally contain various species of *Lactobacillus* and *Bifidobacterium*, which are intended to repopulate the patient's intestinal tract with beneficial bacteria. Probiotics are indicated after chronic digestive disease or extended or excessive use of antibiotics, where the normal bacterial flora would be disrupted. Avian-specific products^a are recommended; however, limited benefit may result from mammalian products or active yogurt culture.

LIVER DISEASE

Liver disease is a common diagnosis in birds. Severe liver damage in birds is commonly seen in a variety of chronic conditions ranging from nutritional disorders to psittacosis. The usual presentation is elongation and bruising of the beak and toenails. Hepatic lipidosis is common in pet birds that become obese due to their sedentary life and malnutritive seed diets. Therefore, nutritional management is crucial in managing liver disorders in birds. Certain hepatic tumors are common in budgerigars, and bile duct carcinomas are found in Amazon parrots. Iron storage disease is seen in mynahs and toucans (see Chapter 15, Evaluating and Treating the Liver).

Several Western herbs have liver-protective and liversupportive properties. Some of them actually stimulate the regeneration of the liver cells. Herbs often perform more effectively as a synergistic formula rather than as the individual herbs. Some of the more common hepatotonic herbs are listed below with their associated benefits and indications.23

Milk thistle seed (Silybum marianum) has been used for 2000 years to treat a wide variety of liver diseases. It is used for treatment of cirrhosis, hepatitis and various forms of hepatotoxicity. Milk thistle is indicated whenever the liver has been damaged or is at risk for damage. Studies have shown that the chemical component, silvmarin, has hepatoprotective properties. It has been found to serve as an antioxidant, decrease free radicals and increase hepatocyte synthesis. Other studies have shown that silymarin inhibits cytochrome P-450 enzymes in liver microsomes. As a result, milk thistle should not be used with drugs metabolized by the P-450 enzyme. There are no other known drug or herbal interactions. Elevations in liver enzymes and bile acids are possible during the first few days of using milk thistle (G.J. Harrison, personal communication, 2003).

Dandelion root (Taraxacum officinale) acts by gently and safely stimulating the liver into an increased state of efficiency. The improved liver function resultantly improves digestion, increases the elimination of waste from the blood and body and reduces the burden on the kidneys and immune system. The root has been used for centuries to treat jaundice. This herb makes an excellent adjunctive therapy with gentle liver support and general nutritive properties.

Oregon grape (Mabonia spp.) is a stronger and faster acting hepatic stimulant than dandelion root. It is indicated in cases suggestive of a deficient liver, such as poor protein digestion, constipation, or poor skin and feather condition. Since this herb stimulates bile production, its use should be avoided in suspected cases of bile duct occlusion. Because of its strong stimulatory effects, it should be used with caution in animals with preexisting liver damage.

Burdock root (Arctium lappa) has been used for thousands of years for a variety of ailments such as eczema, allergies, constipation and toxicity. Burdock root is very cleansing to the blood and stimulating to the liver. It possesses strong antioxidant and nutritive properties. The fresh root has broad antibacterial effects and antitumor action.

Licorice (Glycyrrbiza glabra) neutralizes liver toxins. Scientific articles credit a specific licorice derivative known as glycyrrhizin for successfully treating chronic hepatitis.29 Licorice also has been shown to increase the production of interferon, which is commonly used to treat hepatitis B. Licorice also is used in combination with other herbs as a potentiator, to strengthen the effects of the herbal formula.

In addition, some Chinese herbal formulations have very beneficial effects on the liver. The herbal treatment should be based on a TCVM diagnosis. However, herbal formulations containing bupleurum and gardenia are particularly useful in treating most liver conditions in birds.14 Coptis and Scute Combination (Huang Lian Jie Du Tang) is indicated in cases of viral or bacterial hepatitis with elevated white blood cell counts. 15 Another useful TCVM approach is acupuncture, with acupoints being selected by the TCVM diagnosis.

Liver detoxification is crucial in the management of many primary and secondary hepatic diseases. Certain treatments that are very effective in this detoxification process include herbal formulations and antioxidant therapy and/or rice-based intestinal products such as Ultraclear Plus^e. These products are very useful in the management of gastrointestinal inflammation and allergy, as well as detoxification of the liver. 14 Oligomeric proanthocyanidins (OPC) are powerful antioxidants that scavenge free radicals, thus preventing further cellular degeneration. These products are very useful in chronic and degenerative diseases that involve cellular decay and degeneration. Examples of OPC antioxidants include pycnogenol, grape seed extract, bilberry and citrus bioflavonoids. Herbal formulations for liver detoxification include those described above as well as other herbs that address the individual patient needs.

Liver regeneration is often overlooked in the treatment of liver disease by conventional means. However, several holistic products are available to facilitate liver regeneration. Milk thistle is effective in regenerating hepatocytes in addition to the other benefits discussed previously. Specific products with liver-regenerative potential are

commercially available.¹⁴ Livaplex⁶ is a liver glandular combined with other liver-supportive nutrients. Lipogen⁸ is indicated in cases of hepatic lipidosis.

RENAL DISEASE

Kidney disease is frequently diagnosed in pet birds but seldom specifically treated. Conventional treatments often attempt to correct only the clinical signs, such as lowering the elevated uric acid level in gout cases or reducing urine output in cases of polyuria. Specific diagnosis of the renal disorder is important in developing an effective treatment plan. Certain natural supplements and holistic remedies can be generalized to support renal function and healing of the kidney (see Chapter 16, Evaluating and Treating the Kidneys).

Omega-3 fatty acids (*n*-3 FA) have several renal benefits.⁶ The supplementation of *n*-3 FA can increase renal blood flow and nephron glomerular filtration rate, lower systemic arterial blood pressure and reduce hyperlipidemia. Specifically, the *n*-3 FA supplements reduce total triglycerides and very low-density lipoprotein concentrations; *n*-3 FA reduce inflammation by modulating the arachidonic acid cascade. In addition, *n*-3 FA decrease plasma viscosity. Sources of omega-3 and omega-6 fatty acids include fish oils, flax seed, borage and pumpkin oils. The specific dosing for *n*-3 FA has not been established, but it is suggested that the ratio of *n*-6 to *n*-3 FA may be of greater importance in the overall analysis. One recommendation for dosing suggests mixing flax seed oil with 4 parts corn oil and dosing at 0.10 to 0.20 ml per kg body weight.¹

Various Western herbal remedies have positive effects on the kidneys.²⁹ Dandelion leaf is a potent natural diuretic and excellent nutritive herb. The leaves provide a wide range of vitamins and minerals including potassium, which is commonly lost with mainstream diuresis.

Couch grass serves as an excellent tonic and disinfectant of the urinary tract. It is a soothing, anti-inflammatory demulcent and saponin-based diuretic with mild antimicrobial effects. Couch grass is a specific remedy for chronic or acute cases of cystitis and urethritis in mammals. Herbs with good antimicrobial effects and an affinity for the kidneys include echinacea, Oregon grape and thyme. Marshmallow root is a very safe and gentle mucilage, providing a soothing and protective barrier to mucosal surfaces, including the urinary tract.

Chinese herbal products formulated as Kidney Yin/Yang/Qi tonics are beneficial for certain renal diseases. Classic formulations include Six Flavor Tea, Eight Flavor Tea, Rehmannia 6 and Rehmannia 8. Other Chinese herbal formulations may be indicated, depending on the TCVM diagnosis and concurrent problems. Acupuncture also may be beneficial in managing the

patient, based on the TCVM diagnosis.

Specific nutriceutical products that are marketed for mammals may be useful in birds with similar conditions. These products often include kidney glandulars, vitamins, herbs and enzymes. Arginase is the enzyme necessary for the detoxification of arginine from the kidney. Kidney-supportive products are commercially available. h,i,i,

Recommended dietary changes include lower protein diets, but debate continues regarding the degree of protein restriction that is beneficial and safe. Cases implicating protein as a contributing factor in renal diseases such as gout consistently have very high protein levels. Most importantly is a proper balancing of the diet with normal protein levels and natural, organic foods (see Chapter 4, Nutritional Considerations).

EGG BINDING

Egg binding is failure of the oviduct to pass an egg into the cloaca. In a TCVM perspective, this would be failure of the Kidney Oi to warm the lower burner, thus weakening the oviduct.16 If the egg is stuck due to lack of lubrication in the oviduct, the TCVM assessment would be failure of the Spleen to transport and move fluids where needed, and failure in production of Qi for egg laying. Egg binding is diagnosed as interior Cold deficiency with a build up of phlegm. Potential acupuncture points include SP-6, ST-36, GV-20 and PC-6. SP-6 is chosen to strengthen the Spleen, tonify the Kidneys and calm the mind. ST-36 is the Master point of the abdomen. In addition, ST-36 tonifies the Spleen, strengthens the body and tonifies Qi. GV-20 is used to lift the spirit, clear the mind and tonify Yang. PC-6 calms the mind and tonifies the uterus. Other acupoints are selected on an individual basis, depending on the overall condition of the patient.

Chiropractic adjustment of the pelvis and synsacrum of the hen may be necessary for the proper passage of an egg. Improper nerve innervation of the oviduct can result in poor oviduct contractions with slowing or blockage of the egg-laying process. In addition, the pelvis may not widen properly due to erratic nerve innervation or hormonal imbalances. Relief of the fixations and subluxations will aid in proper nerve innervation of the reproductive tract and ease the egg-laying process.

Proper vitamin and calcium levels are critical in the laying of eggs. Low blood calcium can affect various aspects of egg laying. Calcium is necessary for the production of the eggshell, resulting in soft-shelled eggs when deficient. Calcium also is required for the normal contraction of muscles, including the smooth muscle in the wall of the oviduct. In addition, calcium must be balanced

with phosphorus and vitamin D₃ for optimal utilization and absorption. An excellent source of calcium is calcium lactate, which can be powdered onto soft foods. ¹⁹ Commercial broad-spectrum vitamin and mineral supplements formulated for birds may also be appropriate sources of calcium and related minerals (see Chapter 4, Nutritional Considerations: Section I, Nutrition and Dietary Supplementation, Chapter 5, Calcium Metabolism and Chapter 19, Endocrine Considerations).

IMMUNE DEFICIENCY AND CHRONIC INFECTIONS

Many diseases in birds, as in any other species, begin with a suppressed immune system. The weakened immune system can be the result of physical or psychological conditions. The physical causes include poor genetic constitution, malnutrition, toxic agents or infectious debilitation. Psychological sources may be environmental stress, lack of socialization, sexual frustration and abuse or neglect. The course of disease when exposed to an infectious agent is dependent on the stability of the immune system.

Nutriceutical supplements can boost the immune system by providing proper nutritional support and immune-strengthening components. Apple cider vinegar and *Aloe vera* are two examples of nutritional supplements. Antioxidants boost the immune system by clearing free radicals that otherwise would cause tissue degradation and immune suppression. These products can simply be added to the drinking water or food on a daily basis. *Aloe vera* and most antioxidants can be given as continuous daily supplements, whereas apple cider vinegar is best administered for up to 2 weeks or as needed.

Several Western herbs are effective immune boosters. Certain herbs specifically boost the patient's immune system, such as *Spirulina* sp. and pau d arco. Other herbs support the immune system through their antimicrobial properties. Herbs with antimicrobial effects include *echinacea* spp, goldenseal, Oregon grape and olive leaf.²⁹ These are often used in combination with other herbs as formulations. Certain Chinese herbs possess immune-stimulating properties and antimicrobial effects, including *Huang Lian Jie Du Tang* (Coptis and Scute) and *Yin Qiao San* (Lonicera and Forsythia Formula).¹⁵

The energetic modalities such as acupuncture and homeopathy have strong immune-modulating effects. These therapies treat at the deep energetic level of the patient to boost its innate immune response. As a result, the immune-stabilizing effects are stronger and longer lasting (see Table 10.1 for specific acupuncture points and Table 10.4 for homeopathic remedies in birds).

NEOPLASIA

Tumors and various cancers are prevalent in certain species of pet birds. Budgerigars have the highest incidence of neoplasia in pet psittacines. Various types of tumors and cancers have been reported in many avian species. Therapeutic options are often very limited when approached conventionally. However, many of these cancers can be managed with nutriceuticals, herbal remedies and other integrative therapies.

The general life-style and environment play a vital role in the risk of developing cancer in pets as well as people. ²⁵ A well-balanced and positive emotional environment helps set the tone for health. Toxic conditions, such as smoke, chemical products, strong aerosolized sprays and odors, should be avoided. Exposure to cooking in coated cookware or plastics should be minimized. Provide fresh, clean air in a well-ventilated room and natural unfiltered sunlight. Encourage the bird to fly and/or otherwise exercise.

Good nutrition with a wide variety of healthy foods and a basis of an organic formulated diet should be provided. A variety of organic foods should be offered, including whole grains, raw fruits and vegetables. Foods high in essential vitamins and minerals are often the same as those with good antioxidant and anticancer properties. These include certain vegetables such as asparagus, tomatoes, bell pepper, turnips, kale, cauliflower and broccoli. Certain fruits also provide excellent nutrients, including apples, cranberries, pomegranate, cherry, fig, grapes and mango. Foods rich in fiber and antioxidants are recommended to fight off cancer and support the body's immune system.29 Excellent foods to include in a diet for cancer patients include Spirulina spp, kelp, garlic, onions, tumeric and parsley.25 Foods to avoid include white flour, sugar, meats, fats and dairy products. The diet also should minimize salt intake and excessive vitamin and mineral supplementation.

Herbs assist the body in fighting cancer by providing tonic support of organs and systems. Herbal formulations that support the liver, kidneys and lymphatics help strengthen the immune system by cleansing the body of toxins and metabolic waste products.²⁹ The classic Essiac and Hoxsey formulas were designed for this purpose. These formulations likely have changed over the years, but still contain an array of alterative and cholagogue herbs primed to cleanse the body, improve digestion and eliminate waste products.

Some notable individual herbs with strong anticancer effects include red clover, burdock root and dandelion root. Red clover is an effective anticancer herb; it inhibits the activity of carcinogenic compounds, improves blood

structure and strengthens lymphatic functions.²⁹ Liver-supportive herbs useful in fighting cancers include yellow dock and milk thistle. Yellow dock serves as a strong liver stimulant, while milk thistle protects the liver from harmful by-products of the cancer or cancer therapy. Diuretic herbs like dandelion leaf and nettle aid in removal of systemic waste through the kidneys and urinary tract. Herbs that assist toxic waste removal by soothing and protecting the mucus membranes of the urinary and digestive tracts include slippery elm, marshmallow, flaxseed, psyllium and plantain. Finally, immunostimulant herbs that strengthen the cancer patient's immune response include astragalus and garlic.

Anticancer herbal formulations should be individualized for each cancer patient, based on their specific cancer and the debilitating effects on the body. A typical herbal formulation usually contains three to five herbs. An example of a general tonic anticancer support formulation consists of 2 parts red clover, 1 part astragalus, 1 part dandelion root and 1 part garlic.²⁹ This formula, which can easily be adjusted for the particular patient or condition, provides good systemic support, immunostimulation and cleansing properties.

Nutriceuticals are common among the anticancer remedies on the market for pets and people. Inositol with IP-6^k is a classic example of a nutriceutical product shown

to fight cancer by stimulation of the body's natural killer cell activity.³⁰ Antioxidants are popular additions to holistic cancer therapies because of the stabilizing effects on the patient's tissues produced through the scavenging of free radicals. Antioxidants can be in the gentle form of vitamin C or the very potent form of proanthocyanidins such as grape seed extract or pycnogenol. Certain mushrooms also have shown potential in the treatment of cancer, including Reishi, Maitake and Shiitake.²⁵ Coenzyme Q10 and N,N Dimethylglycine (DMG) are examples of immune-stimulating nutriceuticals with potential use in cancer therapy.¹⁴ These products also are effective in the treatment of chronic diseases, which

debilitate the body's innate healing process.

Low-risk Pest Management

DIANA POST, VMD

Information in this chapter is provided to help ensure that wherever birds are being maintained, pest problems can be dealt with effectively and potentially hazardous conditions can be avoided.

The Environmental Protection Agency's (EPA) classification of pesticides as "low risk" refers to the potential effects in humans, not companion animals or wildlife. This should be kept in mind when a chemical pesticide is being promoted as a "low-risk" alternative. Check with Rachel Carson Council (RCC), 8,16 Biointegral Resource Center (BIRC) 13 or other organizations for non-chemical alternatives that can represent low risks to pets, wildlife and the ecosystem, as well as to people.

Most veterinarians have traditionally used pesticides to control the parasite problems of their patients. However, many of them have adopted a hands-off approach toward routine environmental pest control for ants, cockroaches, rodents, etc, leaving this to the specialized domain of certified exterminators and trusting them to use the products properly. A recent incident serves as a warning to animal health care professionals to reevaluate this practice. The incident happened in January 2003 following use of the intensely toxic rodenticide zinc phosphide. The fatal poisoning of two valuable red pandas at the National Zoo resulted in part from failure of veterinary medical personnel to give sufficiently critical oversight to rodent control procedures.

A promising outcome of the zinc phosphide incident has been the National Zoo's adoption of Integrated Pest Management (IPM) procedures for its animal facilities. IPM in principle involves greater reliance on a variety of low-risk pest management practices and the use of toxic chemicals only as a last resort. Pest problems where companion birds reside can be controlled with similar strategies.

Those in charge of keeping animals healthy cannot afford to delegate pest control measures without first making certain that the intended procedures provide the lowest possible risk to non-target individuals. In the future, with this greater awareness, we are confident that veterinarians will be able to promote low-risk pest management methods for use on premises where animals are under their care. This can happen only if veterinarians understand certain concepts and how they work.

Justifications for avoiding use of chemical pesticides near companion birds can be similar to those given by the United States Environmental Protection Agency (USEPA) for avoiding them around another vulnerable population — children: "Chemical pesticides...may cause a range of harm, such as cancer, (as well as) acute or chronic injury to...(respiratory), nervous, reproductive, endocrine and immune systems..."22 There are additional reasons for bird owners to avoid chemical pesticides. Tests for acute toxicity of pesticide products are performed on rodents. Since birds are generally more sensitive to chemical pesticides than most mammals including rodents, the required tests may not be predictive for toxicity in birds.

Sensitivities to chemicals can vary widely among avian species and it is not possible to designate a single representative bird species to serve as the surrogate for all others in testing pesticide hazards.9 Due to birds' increased vulnerability, they have been used to provide early warnings of toxic environmental conditions potentially harmful to those less sensitive, for example, the canaries were used to protect coal miners from asphyxiation due to methane gases that replace oxygen and tend to collect in coal mines.

Sentinel birds can suffer serious adverse consequences in the process of protecting people. 12,19 If environments are safe for birds, however, then people sharing homes with them will likely benefit as well.

A CASE HISTORY

Before it was banned in 2000 for indoor application, the organophosphate insecticide chlorpyrifos was widely used. Chlorpyrifos treatments for cockroaches in a homebased aviary resulted in the eventual loss of the entire breeding bird population of 15 pairs and their offspring. The toxic nature of the chemical as well as actions by the parties involved contributed to this unfortunate outcome. The applicator called the pesticide "safe" and did not appear to know its potential danger to birds, although the owner specifically questioned him about it. The aviary owner accepted the exterminator's assurances of safety and failed to get a second opinion from those knowledgeable in pesticide toxicity to make certain that the

pest control methods used truly afforded the lowest possible risk to birds. In an ironic twist, the owner was able to collect financial compensation for theoretical damage to his own health that the birds' deaths had indicated.12

COULD CHEMICAL PESTICIDES IN USE TODAY RESULT IN BIRD **INJURIES?**

Although chlorpyrifos and diazinon are no longer available for indoor use in the USA, neurotoxic chemicals (including cholinesterase inhibitors, pyrethroids as well as newer entities such as fipronil) are registered for indoor use and can contact a pet bird through diffusing from application sites such as rugs, furniture, the skin of a dog or cat, and bait stations, even if the bird is removed during the actual application process. Two newer insecticides, fipronil and imidacloprid, have been associated with adverse reactions in people and pets when used in flea control programs (J.H. Gainer, personal communication, 2003). Both insecticides are registered for additional uses in and around the home.

By persisting indoors for months or years on rugs or furniture, certain chemical pesticides may present the potential for adverse effects. When applied outdoors, these same chemicals, plus others registered for outdoor use only, can drift indoors through open windows, contacting a caged bird kept nearby, or they can gain access from air intake ducts or be carried indoors on shoes. Birds and/or their environments may be treated with cholinesterase inhibitors such as the insecticide carbaryl (recommended for mite control) or outdated remedies such as the toxic substance paradichlorobenzene (found in moth crystals) used around cages. Further, the effects of multiple chemical exposures can be additive or even synergistic, with greater likelihood of adverse reactions occurring as a result.

Due to concern over West Nile virus, chemical pesticides may be broadcast from an aircraft or from a land-based vehicle in an effort to reduce mosquitoes. Pet birds (and other sensitive individuals) can be protected from contact with these sprays by closing windows and air intake ducts when the application occurs. If possible, a pet owner should obtain information from local governments, professional pest control companies, landscapers or neighbors who apply pesticides as to time, place and nature of the pesticide product being sprayed close to the home. Greater surveillance of marketed products is needed to collect adverse reaction information. This is especially important for products used in the home and applied to pet animals, such as those products with fipronil and imidacloprid as active ingredients.

INDOOR AIR QUALITY AND PESTICIDES

We have much to learn about the persistence of chemical pesticides indoors. However, what we do know raises troubling concerns even for those chemical agents considered to be less acutely hazardous to birds and people the pyrethroids. Since the recent banning of chlorpyrifos and diazinon for indoor use, chemicals of the pyrethroid class have become more popular. The indoor half-life of long-lasting pyrethroids such as permethrin, deltamethrin, cypermethrin and cyfluthrin may be up to 10 years.¹⁷ Pyrethroids are synthetic versions of the naturally occurring pyrethrins. The latter are much less persistent and less acutely toxic, but they can still evoke allergic reactions.6 A study reported that a percentage of the human population in contact with pyrethroid-treated carpets had vague signs of discomfort (headaches, respiratory disorders, burning eyes, dizziness, tiredness, pain of muscles, bones and joints). In a significant number of subjects, these adverse effects regressed when the carpeting was removed. A scientist working on the study has questioned, "...whether the indoor use of pyrethroids is safe enough to avoid adverse health effects."17 Could birds be harmed due to presence of pyrethroids indoors? Perhaps yes, but we do not know with certainty. However, we do know that a number of alternative methods are available in place of synthetic chemical pesticides for management of pests, both indoors and out.

General Principles and Examples

Approaches to management of indoor and outdoor pests can be very different. Indoors, it is frequently possible to exclude the pest and employ low-risk products when necessary. Biological controls are rarely used indoors. Outdoors, exclusion is less common and biological controls are routinely used, especially by organic farmers and landscapers using biosustainable methods. Soils not designed to grow plants or crops need more pesticides.

BEFORE ANY CONTROL ACTION IS TAKEN

Accurate identification of the "pest" in question is the first step to successful management, especially when dealing with an insect. Entomologists at institutions, local extension service employees or professional pest control personnel can be useful here. Ants, cockroaches, moths, etc, may vary by species in their preferred habitats, food choices and life cycles. Accurate identification should help with selecting effective management methods, deciding whether the organism in question is a true

pest, a non-threatening, neutral insect visitor or even a beneficial insect (distinguishing the latter can be especially important for outdoor pest control); see The Importance of Identifying the Pest and Lessons from a Lacewing below.

INDOOR PEST MANAGEMENT STRATEGIES

Indoor — **Primary Strategy**

After determining that a pest is present and there is a problem, the primary strategy involves preventing the pest from having access to a life-support system consisting of water, food and indoor habitat. Frequently, these measures are the only ones required to significantly reduce or eliminate problem pest populations. They also are prerequisites to further management actions;⁵ see each pest for particulars.

Indoor — Secondary Strategy

Once the primary strategy has been implemented, further action may be needed. Secondary control methods change the pests' habitat while presenting low risks to people, pets and the environment; see each pest for particulars.

OUTDOOR PEST MANAGEMENT STRATEGIES

Outdoor — Primary Strategy

Many lawn and garden pests can be avoided by taking into account the local growing conditions, choosing naturally disease-resistant plants that are also non-invasive native varieties, as well as by using organic fertilizer and compost. Awareness of soil conditions and knowledge of native plant species can help guide landscaping decisions. ²¹ Exclusion is used less frequently than for indoor pests, but if needed it can be accomplished with row covers, netting or fences to keep insects, birds and even deer away from plants.

Outdoor — Secondary Strategy

When pests are found at unacceptable levels and intervention is needed, the secondary strategy makes use of mechanical and biological controls. There are astonishing biological controls (most suitable for outdoors only) for use against pest insects. For example, beneficial insects such as lady beetles (ladybugs) obligingly prey upon aphids and other pests. Females of the non-stinging Brachonid wasps deposit eggs in the body of pests, resulting in the growth of wasp larvae at the expense of the pest. Such insects can be invited to a garden through selective plantings and/or they can be purchased from suppliers (see Suggested Reading for "If You Plant It,"

Table 11.1 | Biological Control Resources

Refer to these resources for more information on biological control products and low-risk pest control methods:

- 1. Rachel Carson Council, Inc (RCC) www.RachelCarsonCouncil.com E-mail: rccouncil@aol.com Phone: 301-593-7507
- Biointegral Resource Center (BIRC) www.birc.org

3. Gardens Alive!
www.GardensAlive.com
E-mail:
gardner@GardensAlive.com
Phone: 812-537-8650

They Will Come" and Table 11.1). Bacteria, fungi, viruses and nematodes also are available for selective pest control. Birds can act as biological controls for insects; so can turtles, amphibians and even fish. For some large herbivores such as deer, contraception can be an effective control method. For mosquito management outdoors, see the discussion below on Mosquitoes.

EXAMPLES OF INSECT IDENTIFICATION

The Importance of Identifying the Pest

A family with two small children moved into a country house where they encountered a large number of tiny red insects that the mother believed to be fleas. Instead of spraying the house, as advised by a local exterminator, the mother contacted RCC for advice. RCC loaned her a yellow/green intermittent light flea trap that she used to obtain specimens of the insects. Her local USDA extension agent identified the insects as red clover mites, non-biting insects. Using her vacuum cleaner, as recommended by RCC, she was able to rid the house of the mites without resorting to the chemical spray.⁸

Lessons from a Lacewing

Environmentalist Anna Edey described how she became an expert in recognizing beneficial insects: "One time I saw a little cluster of 10 to 15 very fine hairs about one-half inch long protruding straight up from a hibiscus leaf. Each hair had a tiny pinhead-sized egg...at the end of it...I decided it looked like a virulent fungus...I nipped off the leaf and discarded it. Later I found out that I had destroyed the eggs of one of the most valuable beneficial insects, the green lacewing." ¹⁶

Indoor Low-Risk Pest Management

ANTS

Ants (Fig 11.1) are one of the most abundant social insect species on earth. They can become pests in buildings as they search for water, food or places to establish

Fig 11.1 | Ants following a crack in the cement to a food source. Ants leave a chemical trail that soap and water can errore

colonies. Carpenter ants can cause considerable damage in moist areas by excavating galleries and establishing residences in wall voids. Ants living outdoors, however, like spiders, can be considered as non-threatening or beneficial through helping to control insects including fleas, termites and fly larvae. Denying access to ants seeking shelter indoors, as well as eliminating access to water and food, can significantly reduce ant populations along with those of other insects.

Preventing Indoor Access

Prevent access by having a sweep on the door where it touches the floor that is in continuous contact with the floor (vertical strips of plastic are not effective at keeping ants out); caulking cracks in the walls and around pipes can prevent ants from coming indoors. In an emergency, duct tape can be used to seal up an ant access area until it can be caulked.¹³ It is important to be sure that the caulk does not contain volatile components that may be irritating to chemically sensitive people and pets.

Preventing Water Access

Ants are attracted to moisture, so any leaks in ceilings or walls and conditions that predispose to moisture should be promptly repaired. These can come from water pipes, downspouts, damaged roofing tiles as well as structures that do not allow for proper ventilation.

Preventing Food Access

Ants are attracted to and consume both sugar and protein, so spilled food should be removed quickly and the area wiped with a soapy water solution. Pet food dishes can be placed in a moat/dish (for example a shallow pie pan) of soapy water to prevent ant access. The soap is important to reduce surface tension so the ants drown.¹³

Food should be stored in ant-proof containers. These consist of a glass jar with a rubber seal or a plastic container with a tight-fitting lid. Ants sometimes get into the refrigerator if the seal around the door is faulty.

Kitchen areas should be kept clean and dry with frequent sweeping, vacuuming and washing up of spills. If water accumulates in a pan under the refrigerator, the pan should be regularly emptied and cleaned.

Dishes can be soaked in soapy water if immediate washing is not possible. Food containers should be rinsed of all food residues before discarding. If possible, trash should be stored outside until collected.

Water, food and droppings in birdcages can attract ants. Birds can be protected by placing a circle of sticky material such as double-sided tape completely around the birdcage stand, since ants do not like to cross sticky material. The same type of sticky material also can be placed around the chain or rope from which the birdcage is suspended. Since birds can become immobilized on sticky tape, it should be placed where birds will not routinely encounter it. Sticky barriers also can be used outdoors to discourage ants, although wild birds can be at greater risk from this placement, especially if they feed on insects caught on the sticky tape. Alternatively, the birdcage stand can be placed in a moat of soapy water.

Ants seem to find extruded polystyrene foam insulation (also known as "blue board") to be ideal for locating colonies. This could be important to those considering remodeling where ants could be a potential problem.

Changing Habitat — Indoor

If ants continue to be present indoors, a non-volatile pesticide can be applied in such a way that children and pets will not be able to come in contact with it. For example, diatomaceous earth or silica aerogel, either alone or in conjunction with boric acid powder, can be placed in floor cracks and crevices and behind cabinets — sites usually accessible only to ants. Dust products should not be inhaled. Contracting with a professional for any applications or employing safety equipment if the homeowner uses them can minimize problems. Diatomaceous earth should not be the kind used in swimming pool filters; it has been polished and therefore is not effective and presents a serious respiratory hazard. Alternatively, bait stations or gel with a pesticide and an ant attractant can be applied in areas not accessible to pets or people, but where ants will pick it up and carry it to the colony. Pesticide bait stations for ants can be placed around the floor if they are not accessible to children and pets. Pesticide concentrations in most bait stations are low enough not to kill the individual ants until they have returned to the colony and shared the bait with other

members. It is important to avoid using bait stations in the same vicinity as pesticides with pyrethrins acting as repellents (see Suggested Reading "What's Wrong with My Bait?").

Baits may take longer to establish control, especially if the active ingredient is an insect growth regulator. Low-risk baits should be placed where they will not come in contact with people or pets, or where a curious bird cannot find one and chew on it. Ants respond to either sugar or protein baits and they may alternate their preferences.

Ideally, the pesticide chemicals in baits should not be volatile, as that would present a hazard to sensitive people or pets. Since new formulations may not follow this rule, monitoring for adverse signs associated with placement of baits is recommended. The chemical fipronil is believed to adversely affect chemically sensitive people when present in bait stations (W. Currie, personal communication, 2002).

An innovative device, the ant guard, has successfully prevented, among other things, fire ants from gaining access to nursing home patients in their beds. In appearance it resembles the metal collar-like rat guard used to block rats from crawling up ships mooring ropes. These initial ant guards have had a chemical deterrent in the form of the pyrethroid insecticide, permethrin, painted on the inside of the collar. If the chemical component could consist of a very low-risk repellent or toxicant instead of permethrin, then it is very likely that ant guards could enjoy a host of additional uses.⁷

Carpenter Ants

A pest control professional probably should be consulted for carpenter ants, the large ants that take up residence in wall voids and woodwork but regularly travel to the outside. Frequently, individuals can be seen traveling along the outside wall from the ground, or up a shrub that is touching the outside wall, and entering the wall through cracks. These ants often remove wood and other substances that pile up in small mounds near the entry sites. These access points should be closed when the colony is treated. Indoors, the colony can be located by listening with a stethoscope for the characteristic noise made by the ants. The most easily heard sounds made by carpenter ants are intermittent clicks. The chewing sounds that they produce are softer and harder to detect. These sounds can be generated during day or nighttime hours (J. Ward, personal communication, 2004). Once its parameters are identified, the colony can be treated with boric acid powder and/or diatomaceous earth, blown into the wall void through a series of strategically placed holes drilled on the inside wall of the area they occupy. Afterward, a professional should fill in the holes.

Fig 11.2 | Palmetto bugs (roaches) are common in the tropics around dense foliage. Food sources can encourage them indoors in any setting.

Following the wall treatment, baits can be used until all signs of the carpenter ants are gone.

COCKROACHES

Cockroaches (Fig 11.2, 11.3) like buildings because they provide all the essential elements needed for survival including shelter (sometimes called harborage), moisture and food. Cockroaches are strongly attracted to water. Although they can survive without food, they must have frequent access to water.4 They prefer shelter where they can touch the area above them with their antennae, such as areas under cabinets.4 Cockroach problems almost always indicate the presence of excessive moisture and poor sanitation, as well as access to harborage or shelter. Reducing access to indoors, to moisture and food can prevent infestations. Otherwise, cockroach populations are very difficult to manage because small residual populations can survive in even the most sanitary of environments. Further, residual populations can explode into major problems. The use of chemical pesticide applications can never be regarded as a substitute for either prevention or good sanitation practices. Pesticidal suppression of cockroach populations without a change in the environmental conditions that support them only gives a false and temporary sense of security and may result in chemical resistance in pest populations.5 Cockroach food can consist of that eaten by people and pets, as well as soiled paper and glue.13

Preventing Indoor Access

In a home or apartment, good barrier maintenance is mandatory if cockroaches are to be denied access. This requires elimination of the holes and cracks that cockroaches use to gain entry. Before sealing see Boric Acid below. Access can be denied to cockroaches and other insects through the following measures: installing tight-fitting windows, doors, screens and door sweeps; caulk-

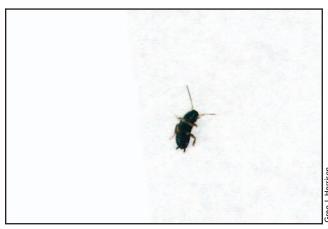

Fig 11.3 | The small (German) roach is much harder to eliminate than its larger cousin. After eliminating food sources, a thorough (steam) cleaning and sealing of cracks is a must.

ing all exterior and interior cracks and holes in foundations, walls, sills, sinks, gas, water and electrical lines; covering prong holes in electrical outlets at all times; screening air and ventilation vents, open sewer lines and drains. Stainless steel baskets can be used in sink and floor drains to prevent entry of cockroaches from sewers.¹³ Even the tiniest crevices must be attended to since an adult roach can hide in cracks as small as one-sixteenth inch and young nymphs can get through a void even smaller.

Preventing Water Access

Leaking faucets and pipes should be repaired. If possible, standing water should be eliminated or covered. Screens should be placed on fish tanks.¹³

Preventing Food Access

Foods should be stored in insect-proof jars with rubber gaskets or tight-fitting lids and/or be kept in the refrigerator. Food and grease should be removed each day from stoves and counters. (A fingerprint left on a countertop by someone who has eaten fried chicken can feed a roach for several days.5) Thorough cleanup of food particles on and under tables and counters should be done as soon as possible after meals. Dishes not promptly washed should be immersed in soapy water. Pet food, caches of crackers, nuts or even cough drops should be stored in the refrigerator between meals and dry food should be stored in plastic containers with snap-on lids.13 Garbage should be placed in a plastic container with a tight snap-on lid. 13 Refrigerators can pose weak links in cockroach management programs because they provide heat, harborage around coils, a constant water supply and hiding places that are difficult to treat.4

School for Shaft Squatters

A school cafeteria was being switched to low-risk pest

management and all the appropriate steps had been taken to restrict access, remove sources of water and food, and treat known harborage, but cockroaches were still present. Finally, the pest management manager checked the hollow steel tube legs of the cafeteria tables and found a previously overlooked cockroach harborage. When this site was treated the cockroach problem resolved (W. Currie, personal communication, 2003).

Advantages of Cleaning

Regular vacuuming reduces cockroaches' food sources. Cleaning out clutter reduces nesting and breeding sites, as well as possible food sources such as glue and soiled paper.

Changing Habitat

At the first sign of a cockroach problem, sticky traps can be placed to detect the pests' preferred shelter sites and later for monitoring to determine whether control efforts have succeeded. The traps should be non-toxic and placed along the edges of walls or counters where roaches normally travel. ¹³ Cracks or crevices in floors or walls can be treated with boric acid before being closed by caulking or other means. See Boric Acid below.

FLEAS

The flea usually infesting USA homes is the cat flea, *Ctenocephalides felis*. Adult fleas most commonly obtain blood meals from mammalian hosts including dogs and people as well as cats. These organisms are parasites requiring a blood meal to reproduce. Fleas spend part of their life cycle on the host animal, but can develop off the host so long as they have access to droppings from the adult flea, since the droppings contain partially digested blood and serve as a food source for immature fleas. Fleas can reproduce indoors where the pet sleeps or rests, as well as outdoors during the warmer months in shaded areas such as crawl spaces under houses. Since fleas are parasites, they do not depend on nonliving sources of food to survive.

Preventing Indoor Access

Animals coming into the house for the first time or after being away at a kennel or in transit should be inspected and, if necessary, bathed or vacuumed for fleas before being given access to indoors. This helps prevent seeding of the premises. If people have visited a known flea-infested area, they should change clothes or vacuum their clothes upon entering the house. The car and pet carrier should be vacuumed and washed if necessary. Once the vacuum has been used it needs to be cleaned and treated for fleas or they will escape. Residents can check for fleas indoors by walking around with white

socks and looking for small, black, moving forms. Flea problems in cats can be avoided by keeping them indoors or allowing access to a deck, screened or otherwise not in contact with the ground, to prevent the cats' picking up fleas from infested ground sites.

Changing Habitat — Indoors

Washing pet bedding in hot water and drying in a dryer where possible along with vacuuming and disposing of the vacuum contents so that the eggs do not continue to develop inside the vacuum bag can remove fleas. Frequent cleaning of non-carpeted floor areas and anywhere the pet sleeps will help reduce numbers of developing fleas. Furniture and rugs can be shampooed in cases of heavy flea infestation.

A light trap for fleas can be used to locate high population levels and measure control methods. Light traps are cardboard box-like stationary devices consisting of a light source to attract the adult fleas, as well as a sticky surface, which fleas encounter and on which they become caught when they jump toward the light.

Use of a fine-toothed comb (32 teeth per inch) is recommended when combing a pet for fleas. It is best to comb pets on a white sheet to catch any eggs or larvae removed by the flea comb. Fleas should be dropped in soapy water after removing them. When combing is completed, the sheet should be picked up by the corners and taken to be washed. Cats and dogs can be bathed using flea shampoo and, before they are completely dry, combed to remove fleas while the fleas are still immobilized from the bathing procedure. Washing flea-infested clothing or other material in hot water and drying in a dryer will destroy all stages in the flea life cycle. Dogs and cats can be treated with an oral flea control medication, Program, that prevents fleas from developing.

Changing Habitat — Outdoors

If a pet goes outdoors, grass and vegetation should be kept short in places where the pet sleeps or rests. Sunlight can inhibit flea development. If possible, pets and wildlife should be prohibited from having access to areas such as porch crawl spaces, which are permanently shaded and ideal for flea development. A strain of the nematode *Steinernema feltiae* can attack larval stages of fleas²⁰ (A. Pye, personal communication, 2003). The nematodes are sprayed outdoors on the soil where they can take up residence and help reduce numbers of viable fleas. Products containing this nematode species are commercially available^a (see Table 11.1 for Gardens Alive!, another resource for this organism). Nematodes are not intended for use as indoor flea controls.

INSECT INFESTATION OF FOOD

Larvae of beetles and moths and grain mites can infest stored grain or birdseed. Some insects lay their eggs in the grains in the field and therefore are present as eggs in seeds and even flour. The heat associated with processing the grains usually eliminates the eggs from pellitized and extruded products. Many of these insects can crawl down the threads of an ordinary screw-cap jar, or penetrate a single paper or cloth bag, so it is necessary to use a glass jar with a rubber gasket or containers with tight-fitting lids to exclude them. For storage, bulk seed should be divided into 5- and 10-lb. containers so only small amounts will be lost if some of it becomes contaminated. One solution is to use 5-gallon buckets of the type used by bakeries. These buckets usually have tightfitting plastic or metal lids.13 Food should be stored in a cool and dry environment. Most pests will not infest products if the humidity is below 6%.13 An inexpensive instrument can measure the humidity in the storage area. Alternatively, grain and seeds can be stored in the freezer. Food spills should be promptly cleaned up.

Preventing Indoor Access

At the time of purchase and/or when they are first brought into the home, foodstuffs should be inspected for possible mite infestation in the form of web-like structures on or around the material.13

Changing Habitat

Bacillus thuringiensis (B.t.) is a commercially available bacterial species that causes disease in certain insects by acting as a stomach poison. B.t. can be applied to stored grains for protection against the larval form of the Indianmeal moth. These insects seldom feed below a surface layer more than 4 inches deep in a grain bin, so B.t. can be effective if applied to the surface. 13 See Low-Risk Agents below.

Parasitoids such as the tiny Trichogramma can kill the egg stages of the moth. This approach could be very helpful for controlling long-standing infestations in the home or aviary that have proved resistant to the normal physical or sanitary methods already described.13

All stages of the Indianmeal moth are killed by freezing at 0° F (-17° C) for 4 days. A pheromone trap for monitoring is commercially available. Once infestation is found, the material can either be placed in a freezer or heated to kill pests. The material should then be discarded. Seriously infested products with webs are often secondarily contaminated with toxic levels of molds. Therefore, they should not be fed after freezing or heating.

Fig 11.4 | Spiders are often misunderstood and killed. Moving them, removing their webs and reducing the insect attractions that cause spiders to be attracted contributes to insect control in the long run.

CLOTHES MOTHS

The larvae of clothes moths attack various types of household material including blankets, upholstery and carpets. Clothes moth larvae avoid light and require material stained with food or sweat to provide the proper nutrients to grow. These moths do not attack clean clothes or fabrics stored in sealed containers. Carcasses of dead mice in wall voids can attract moths. Unoccupied bird or bat nests in attics can be a source of clothes moths and other insects.

Infestation by clothes moths can be managed chiefly by prevention. Clothes should be thoroughly cleaned before storing in tight containers. Vacuuming around the home and furniture is a way of controlling moths. Exposure to heat is a direct way to kill clothes moths. If the temperature can be maintained at or above 100° F (37° C) for several hours to days, all stages of the insect can be killed. Attics can often reach such temperatures in the summer. Extremely cold temperatures (sealed bags in a freezer) for several days also can control clothes moths. Traps to monitor for the presence of clothes moths can be hung in the closet as an early warning device. 13

YELLOW JACKETS

Yellow jackets are a form of wasp that usually nest in the ground, but they can at times nest in walls of homes. Indoors they can actually excavate through plaster and in rare cases penetrate into adjacent rooms. Professional control using low-risk methods and performed at night to minimize disturbing the insects can be effective. When proper precautions are taken so as to not endanger residents, injecting a spray of pyrethrins and diatomaceous earth and then closing the access to the outdoors can be effective in eliminating the colony from a wall void. See also Traps to follow.

SPIDERS

The presence of spiders can indicate that there are flies in the house. Spiders are useful and should be removed to outdoors whenever possible (Fig 11.4). Spiders can be removed to the outside mechanically with a glass and a piece of stiff cardboard or by using a vacuum that will usually kill most spiders. Once the flies have been controlled and the spiders removed mechanically or by vacuum, they can be kept out by the same exclusion methods as those used for cockroaches and ants, and by caulking and using screens and door sweeps. There is usually no need to use a chemical spray.

MICE

Adult house mice can weigh from 0.5 to 1.0 oz (15 to 30 g). House mice breed year-round under optimum indoor conditions. Outdoors, these mice are seasonal breeders in the spring and fall. They are active primarily at night but also can be seen moving about during the day. Mice thoroughly investigate any change in their territory.4 They can squeeze through openings slightly more than one-quarter inch in diameter. They prefer cereals to other food items. Management and prevention of infestations by house mice is a three-part process: mouseproofing, sanitation and population reduction indoors with traps. When a mouse population already exists, some kind of lethal control is necessary. Otherwise, the reproductive capability of the mice and their remarkable ability to find food in almost any habitat will keep their populations steady or increasing.4 The practice of using poisons on mice may lead to dead mice in wall voids, resulting in a moth infestation that can spread to clothing. Clothes moths are often attracted to the carcasses of dead animals. Other insects and bacteria can result from poisoned, decomposing mice; and pets, including pet birds, can be at risk from feeding on the dead mice or the rodenticide used for rodent control.

Preventing Indoor Access

Mice are found around human housing, especially in rural habitats. During the autumn and winter, they readily move into buildings that are not made rodent-proof. All holes must be sealed to limit the movement of mice into and through a building. Holes in foundation walls for pipes, utility lines and vents should be plugged with quarter-inch hardware cloth, copper mesh or steel wool. Doors and windows should fit tightly and be caulked if necessary.

Preventing Food Access

Practicing good sanitation is a way to reduce the food supply. It enhances the effectiveness of traps and makes detection of a mouse infestation easier. Bulk foods should be

stored in mouse-proof containers or rooms. Stored materials should be kept away from walls and off the floor.

If corn gluten herbicide is being used, it should be stored over the winter in a container that mice cannot penetrate. Any birdseed should be stored in tight containers or kept under refrigeration.

Changing Habitat — Indoors

Types of Traps

When used correctly, snap traps are very effective for controlling mice. Traps must be set in the right places, in high numbers and in the right position (see below) or mice will avoid them.⁴ If used properly, snap traps inflict less suffering than do glue traps and possibly the so-called humane box traps, since if animals are released in a distant territory they will likely be attacked as aliens by resident mice.

Setting Traps

The territory of mice rarely extends farther than 30 feet from the nest, and more often is about 10 feet. If mice are sighted throughout a building it usually means there are numerous locations where traps should be set. Traps should be placed wherever there are obvious signs of mice. Probably the biggest mistake made when trapping mice is not using enough traps. Traps should be set every 3 to 6 feet in prime mouse habitat. They should be set in a three-dimensional sphere about 10 feet in diameter around the signs.

Baits

Choosing good baits for mice and rats increases the effectiveness of mousetraps. Peanut butter (the chunky kind) is considered one of the best baits; food baits should be fresh to be effective. A cotton ball, which females like to use for nest material, also can be used. The cotton should be tied securely to the trigger.

Outdoor Low-Risk Pest Management

WEED MANAGEMENT

Synthetic chemical pesticides do not need to be routinely used against most types of weeds. 11 For poison ivy, digging out the root and/or applying a 9% solution of vinegar (used for pickling) are effective. For other broadleaf weeds, corn gluten meal (Fig 11.5) is an effective preemergent herbicide and can be used in spring and fall. Herbicidal soap is available for spot-treating weeds. On paved surfaces, boiling water, steam, a flamer or other heat source can be used to remove unwanted vegetation.

Fig 11.5 | Corn gluten meal serves as a preemergence herbicide and then deteriorates into a soil nutrient supply source.

INSECT PESTS OF THE LAWN AND GARDEN

In many instances, the need for chemical insecticides can be replaced with management strategies and natural enemies of pests. Biological controls are commercially available. Beneficial insects also can be encouraged by providing certain plants in the garden needed by the insects for stages of their life cycles when they are not preying on pests (see Table 11.1 for RCC Web site for further details and information on grubs in the lawn; see also reference 16 and Suggested Reading "If You Plant It They Will Come").

MOSQUITOES

Mosquito Management

In most naturally occurring streams or even backyard ponds, living organisms such as fish, amphibians and insects feed on mosquito larvae and prevent the emergence of adults. Biological control of adults includes birds and bats.3 In artificially occurring standing water, the mechanical emptying of containers every 4 to 5 days is the best prevention for adult mosquito emergence. When water cannot be changed due to high volume and/or there is not a system with naturally occurring biological controls, B.t. preparations (see below) can be used to kill off the developing mosquito larvae in standing water, as will dish soap or a thin coating of olive oil.

It is most important to clean out rain gutters so that they empty freely after a storm. Habitat should be provided for wildlife such as birds, bats and dragonflies (Figs 11.6,

Fig 11.6 | The beneficial dragonfly acts as flying insect control by consuming large numbers of pest insects.

Fig 11.7 | Swarms of dragonflies are seen seasonally during the height of the pest insect season.

11.7) that act as biological controls by consuming adult mosquitoes. For special outdoor occasions, there are mosquito-trapping devices, some quite successful, that generate carbon dioxide, heat and synthetic attractants.

Effective natural mosquito repellents include garlic oil, catnip and botanicals such as mint, citronella, geraniol, linalool, elemol (from the Osage orange tree), etc, used singly or in combination. There also is the synthetic chemical repellent DEET (best used at 30% concentration or less, applied to clothing, not to skin).

Mosquito repellent products can be sorted into three categories according to where they are applied: those placed on the clothing or skin; those dispersed into the air near people by a battery-powered device; and those applied to the ground area-wide, as granules or liquid or as liquid sprayed at ground level. More research is needed on the effectiveness of repellents in various delivery systems, even for active ingredients of the natural, non-synthetic type. The area repellent products require more research into their potential environmental hazards. Could they, for example, adversely affect beneficial insects and other life forms? See Garlic Juice Products below.

Low-Risk Agents

BACILLUS THURINGIENSIS (B.t.)

B.t is a spore-forming bacteria named for a town in Germany. Its insecticidal properties were first found in 1911 in diseased flour moths. *B.t.* contains a protein (endotoxin) that is toxic for many caterpillars and other insect larvae. Varieties have been discovered that affect a relatively narrow range of hosts, specifically mosquitoes, as well as certain moths and beetles. *B.t.* products in general lack toxicity for non-target species and the natural insect enemies of pests. *B.t* has been granted an exemption from establishing a tolerance for use on food crops due to its low toxicity for humans when taken by mouth.¹³

However, spray preparations of *B.t.* products have apparently been associated with adverse reactions when inhaled by certain sensitive individuals. Although in most cases *B.t.* would not be recommended for home use indoors against moth infestation, it is available commercially for that situation as well as for outdoor use against mosquito larvae, gypsy moth larvae and other garden pests. ¹³ *B.t.* preparations used for mosquito control include dunks and granules intended for use in standing water.

BORIC ACID

Boric acid is a crystalline material derived from borax, (a combination of sodium, boron and oxygen mined from the earth). It acts as a stomach poison when ingested by the cockroach or ant causing the insect to starve, which can take 5 to 10 days. It can be toxic to mammals when ingested in high doses. Boric acid does not represent a volatile danger in its powder form. It is considered "virtually vaporless." 13 It must be kept away from food, children and pets including pet birds to prevent oral consumption. Those applying boric acid powder should wear a dust mask, gloves, long sleeves and eye protection. It is considered a low-risk alternative when used indoors and placed in areas not accessible to pets or people, provided that precautions are taken and/or the formulation does not include another active ingredient or inert component that may volatilize and induce adverse effects through inhalation or dermal contact. If boric acid is applied to cracks, crevices and wall voids, the areas should subsequently be sealed by caulking or closed off by another means so that it will not present a problem to non-target individuals.¹³ Boric acid remains active for months and cockroaches appear not to have developed any resistance after 50 years of use. Boric acid can be toxic under conditions of high exposure, so it is important to limit access.

CORN GLUTEN MEAL

The pre-emergent weed suppression qualities of corn gluten meal (CGM) were discovered in 1987. CGM, a waste product of corn milling that has been used in animal feed, is 60% protein and 10% nitrogen by weight. Protein is the active ingredient in CGM. It inhibits the growth of roots at the time of a plant's germination.

Timing of the application of this pre-emergent herbicide is very important. The precise moment in the year most advantageous for CGM weed control varies with growing conditions. The local cooperative extension service can be very helpful with advice on when best to apply CGM. For example, in the Northeast, to manage crabgrass in a lawn situation in the spring, CGM should be applied at the time of the crocus bloom and before the forsythia bloom takes place. If applied later, after the weeds have already germinated, the nitrogen in CGM could help the emerging weeds thrive (M. Talbot, personal communication, 2004). See Table 11.1 for Gardens Alive!, a resource for CGM. The use of CGM as an herbicide is patented by Iowa State University.

DIATOMACEOUS EARTH

Diatomaceous earth is obtained from the fossilized silica shell remains of diatoms, marine plankton. It has abrasive, sorptive and desiccant properties. It can be used alone or in conjunction with boric acid and/or pyrethrins (naturally occurring pesticides from chrysanthemums — see below). As with any dust preparation, a mask, goggles and gloves should be worn by the applicator to protect the eyes, respiratory system and skin.¹³

NEMATODES

Nematodes are tiny worms. Most species live in the soil and a few species are internal parasites of higher organisms including man. When fleas are replicating outdoors, certain species of nematodes may be effective in inhibiting their development^a.

PARASITOIDS

See Clothes Moths.

PYRETHRINS

Pyrethrins are short-lived biological pesticides isolated from chrysanthemums. They act as neurotoxic agents and have the ability to paralyze insects. They can be used in conjunction with diatomaceous earth or silica aerogel (see below). They are usually formulated with the agent piperonyl butoxide to prevent metabolism of the pyrethrin. Untoward allergic-type reactions in people or pets may take place when pyrethrins are used. Pyrethrins have very low acute toxicity for most

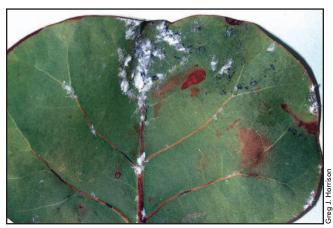

Fig 11.8 | Leaf mold on this sea grape plant is a result of mites and the soil in the pot is not supporting healthy plant growth. Reporting and an application of liquid dish soap are considered an effective control.

mammals and birds, but they are highly toxic to fish.2

SILICA AEROGEL

Silica aerogel is an amorphous, non-abrasive, chemically inert, dust-like material. It results from the reaction of sodium silicate and sulfuric acid. Silica aerogels can absorb water and oil. When used as insecticide, it is believed to absorb the waxy protective coating on an insect's cuticle — an action that can result in dehydration and death of the insect. Silica aerogel particles are capable of irritating human lungs and eyes, so a dust mask, goggles and gloves should be worn during application.¹³

SOAPY WATER

A soap solution reduces the surface tension of water; as a result, insects are unable to float and they drown. Some plant pests are deterred by the use of soapy water applications (Fig 11.8). (See Ants - Preventing Access to Food).

GARLIC JUICE PRODUCTS

Neither the author nor the editors have any experience with garlic products. A veterinarian in the Netherlands states that one product^c is very effective in controlling mosquitoes in the yard (J. Hooimeijer, personal communication, 2003). The smell is a potential problem for people who are sensitive to garlic. Originally garlic was developed for control of pest insects on organic vegetable crops. The farmers using the product found mosquitoes were no longer a problem in the fields for rather long periods of time after its use on vegetables.

TRAPS

A variety of traps are commercially available including the following:

- A yellow jacket outdoor trap for use away from the area where people are gathering, consisting of one-way ports and baited with cat food, sugar-containing cola drinks or meat. After yellow jackets enter the trap, placing the trap in the sun will kill them. This should be used only during the late summer when yellow jackets are aggressive toward people and their food. Traps can be purchased from local hardware stores.
- Ant and cockroach indoor traps have attractants and insecticides at sufficiently low concentrations for ants and cockroaches to carry the poison back to members of the colony without endangering other life forms.
- A mosquito outdoor trap^b uses propane to generate carbon dioxide and heat. In addition, certain models may contain specific attractants such as octanol. These traps are designed to lure and kill only insects that seek a blood meal. They spare the non-biting forms.
- Moth traps use pheromones.

Evaluating and Treating the

Cardiovascular System

MICHAEL PEES, Dr med vet, German vet spec for birds/reptiles; MARIA-ELISABETH KRAUTWALD-JUNGHANNS, Prof Dr med vet, Dr habil, Dipl ECAMS, German vet spec for birds/reptiles; JENS STRAUB, Dr med vet, German vet spec for birds/reptiles

Anatomical Considerations

The avian heart is located within the cranial part of the thoracoabdominal cavity parallel to the spine in close proximity to the sternum. No diaphragm is present and the apex of the heart is surrounded by the liver lobes. The pericardium covers the heart and normally encloses a small quantity of fluid within the pericardial space.

The anatomy of the avian heart is similar to the mammalian heart, although some morphological peculiarities exist. As in mammals, it is four chambered and functionally divided into the right and the left sides each consisting of an atrium and a ventricle. The right ventricle is sickle-moon shaped and surrounds the left ventricle. The wall thickness of the ventricles changes from the base to the apex of the heart (for measurements see Table 12.6). The triangular right atrioventricular (AV) valve is muscular and unlike the right atrioventricular valve in the mammalian heart, does not contain chordae tendinae. Contraction assists emptying of the right ventricle during systole. In some species, the right cranial and the caudal V. cava form a Sinus venosus that is separate from the right atrium. In contrast, the ascending aorta curves to the right in birds rather than the left side of the body in mammals. 2,25,26,41,44,45,53

Diagnostics

Diagnosis of cardiovascular diseases in cage and aviary birds is complicated by several factors. Only a few systematic investigations on post mortem diagnosis of cardiac diseases have been conducted. 4,24 All descriptions of ante mortem diagnostics are case reports, based on individual experience. Documented normal reference values are rare. Clinical signs of cardiac disease in birds are often nonspecific and may be accompanied by other concurrent disease conditions disguising the clinical picture. Diagnostic techniques in living birds are limited by the size of the patients and high heart rates. Fortunately, within recent years, modern imaging techniques (like echocardiography) have been evaluated in birds and initial reference values for the assessment of cardiac function are now available. Since these techniques require special equipment and experience, they are not commonly performed in practice. Nevertheless, the practitioner should be aware of the diagnostic potential of ultrasound and other imaging techniques in avian cardiac disease.

Birds with acute circulatory problems have to be handled as emergency cases. Handling should be kept to a minimum and diagnostic procedures be carefully selected. The bird should be maintained in an upright position to prevent circulatory failure. Echocardiography may therefore be less stressful in these patients than radiographic examination.

CLINICAL EXAMINATION

The clinical diagnosis of cardiovascular disease in living birds can be difficult. There is no palpable pulse in birds. In addition, auscultation, an important standard technique in mammals, is difficult to interpret in birds.

Birds suffering from cardiac disease are often presented to the veterinarian with a history of weakness and lethargy. In some cases, cardiovascular failure can be suspected on the basis of bluish discoloration of the periorbital skin (especially in African grey parrots) and abdominal distension. Nonspecific symptoms like dyspnea and exercise intolerance may also lead to a tentative diagnosis of a cardiac problem and provide an indication for further diagnostic procedures.

STANDARD RADIOLOGY

Radiology is a commonly performed and well established imaging technique in avian medicine. It may (often by chance) disclose signs of cardiovascular disease and indicate the need for further diagnostics, especially echocardiography. Position, size and shape of the heart and other internal organs as well as the radiodensity of the large vessels should be assessed.

Alterations of cardiac shape and size are often seen as an enlargement of the heart silhouette. This can be caused by different etiologies (eg, hypertrophy, dilatation, pericardial effusion, aneurysm, inflammation or neoplasia). Radiographic differentiation between these etiologies is difficult. In cases of an existing pericardial effusion, the conventional radiograph may reveal cardiomegaly with an irregular cardiac silhouette.

An increased radiodensity of the large heart vessels can be seen on the ventrodorsal projection as roundish shadows superimposed on the base of the heart and in the lateral projections as an enlarged and radiodense aortic shadow. These findings may indicate atherosclerosis, whereas their lack does not prove the absence of pathological alterations.

Furthermore, radiographs may reveal secondary changes in other organs, such as increased radiodensity of the lungs, enlargement of the hepatic silhouette, or ascites in the case of congestive heart failure (see Fig 12.10). Ascites can also mask the radiographic detail of the thoracocoelomic cavity and the air sac shadows may be decreased and/or displaced.

In birds, measurements of the length and width of the cardiac silhouette on radiographs are limited. Initial examinations have been performed in Canada geese and psittacines. 12,46 Measuring the length of the cardiac silhouette is often complicated by superimposition of the apex of the heart on the liver on both the lateral and ventrodorsal projections or the ventral aspect of the heart on the sternum on the lateral projection. Measurements of the width of the cardiac silhouette (see "h" in Fig 12.1) should be performed on the ventrodorsal radiograph with exact superimposition of the keel and the spine. To assess the width of the cardiac silhouette, the measured value should be taken at the level of the maximum width of the cardiac silhouette, and compared to the maximum width of the thorax (see "t" in Fig 12.1). The sternal length should be taken on the radiograph or on the patient using a standard sliding calliper. In medium sized psittacines (approximately 200 to 500 g) the width of the cardiac silhouette should be approximately 36 to 41% of the length of the sternum or 51 to 61% of the width of the thorax respectively. There is a strong correlation between the width of the cardiac silhouette and the width of the thorax. 46 In Canadian geese the width of the cardiac silhouette is 47 to 57% of the width of the thorax.12 This study also showed that the movements of the thorax due to respiration are not as important as might be expected.

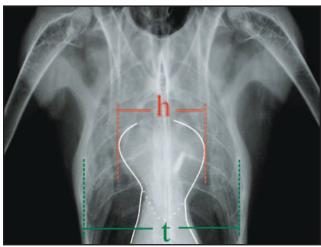

Fig 12.1 | Schematic illustration of the distances to be measured for the evaluation of the avian heart on ventrodorsal radiographs (h = maximum width of the heart size, t = width of the thorax at the level of the maximum width of the cardiac silhouette (microchip can be seen in the left pectoral muscle).

ANGIOCARDIOGRAPHY

Although few reports about the use of angiocardiography in birds exist, the authors' initial experiences show a high potential value for its use in diagnosing cardiac problems. Angiocardiography cannot replace echocardiography but it might give additional information, especially in birds with insufficient detail demonstrated on echocardiographic examination. Examination of the heart vessels is another indication for angiocardiography. In one report, an aneurysm of the right coronary artery was demonstrated in a white cockatoo (*Cacatua alba*) using angiocardiography.⁵²

Angiocardiography should be performed under anaesthesia. A venous catheter is placed within the jugular or basilic vein. Iodinated contrast media (eg, Iopamidol, 510 mg/ml adequate 250 mg iodine per ml) is used according to mammalian angiocardiography, but the dosage in birds (2-4 ml/kg of pamidol ie, 1,020-2,040 mg body mass) is twice as high as commonly used in mammals. Administration rate in medium sized birds should be approximately 1 to 2 ml of contrast medium per second.

Due to the rapid heart rate in birds, assessment of contractility may be difficult to evaluate, but hypertrophy (ventricles), dilatation (ventricles, atria), stenosis (vessels, valves) and aneurysm (vessels) can be detected (see Fig 12.2).

ECHOCARDIOGRAPHY

In veterinary medicine, echocardiographic examination has become a very important diagnostic tool, and is indicated for assessment of cardiac function and the structure of the heart. For a long time, due to anatomical peculiarities (especially the position of the airsacs),

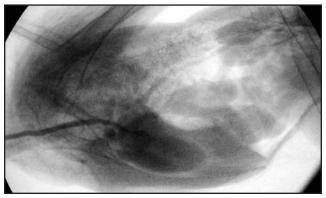

Fig 12.2 | Angiocardiography: filling of the heart in a common buzzard (*Buteo buteo*).

echocardiography has been considered inaccurate and difficult in birds. Bone and air block the passage of ultrasound waves. Standardized views and protocols for mammals recommended by the American College of Veterinary Internal Medicine⁵⁰ cannot be used in birds and comparison of the measurements with those in mammal or human medicine are not valid.¹⁵ However, in recent years, case reports regarding the use of echocardiography for diagnosis of cardiac disease in birds have demonstrated the potential of this diagnostic procedure.^{29,30,47,52} Initial studies have been conducted and standardized protocols for echocardiographic examination in avian patients have been established.^{15,34,46,47}

Improved technology has produced ultrasound equipment that is effective and affordable for avian echocardiography. Parameters of these machines should include

- 1) minimum 100 frames/second
- 2) Doppler function
- 3) microcurved or phased array probes
- 4) minimum 7.5 MHz frequency

On avian patients that are tolerant of restraint, echocardiography can be performed awake; stress-sensitive birds should be anesthetized.

Because the food-filled gastrointestinal tract might be interposed between the scanner and the heart ideally the GI-tract should be empty. Therefore it is recommended to fast the bird before ultrasound examination. Granivorous birds should be fasted for about 2 (small psittacines) to 12 (pigeons) hours. Raptors should generally be fasted for a longer period.

Echocardiographic measurements should be done in relation to the patient's size. Two parameters should be determined: first, the bird's weight (although this might be misleading in seriously ill birds that are emaciated), and second, the length of the sternum, taken on the radiograph or on the patient using a standard sliding calliper. Simultaneous ECG recording and triggering is

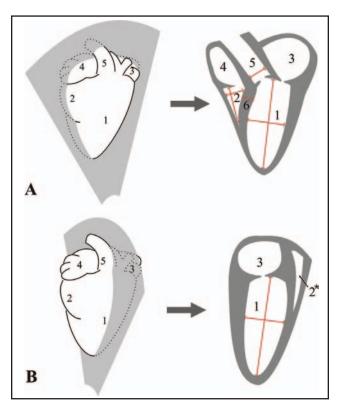

Fig 12.3 | Two-dimensional echocardiography, schematic views: ventromedian approach, horizontal (a) and vertical (b) view. Important measurement points, values see Tables 12.1 and 12.2. (1 = left ventricle, 2 = right ventricle, 3 = left atrium, 4 = right atrium, 5 = aortic root, 6 = interventricular septum, * = no assessment possible in B view)

recommended to allow measurements at defined stages of the heart cycle. For the examination, birds should be held in an upright position in order to minimize stress and its influence on the cardiovascular system.

Because of the avian anatomy, suitable echocardiographic windows to the heart are limited. There are two possibilities: the ventromedian and the parasternal approach.¹⁵ In psittacines and raptors, the ventromedian approach is routinely used. With this approach the homogenous liver tissue serves as an acoustic window. The scanner is placed on the midline directly behind the sternum and the beam plane is directed craniodorsally. In birds with sufficient space between the last ribs and the pelvis (eg, pigeons), the parasternal approach can be used. The transducer is placed on the right side of the body, since in the left part of the thoracoabdominal cavity, the grit-filled ventriculus is present and often makes visualization of the heart impossible. The probe is placed behind the last ribs and the plane is directed craniomedially.

With the ventromedian approach, two longitudinal (comparable to "long axis" in mammal echocardiography) views of the heart are obtained (Fig 12.3). The vertical view (corresponding to the "two-chamber view")

shows the heart lying on the inner surface of the sternum. The horizontal view ("four-chamber view") is produced by a counter-clockwise 90 degree rotation of the scanner.

B-mode-echocardiography (2-D-echocardiography)

Due to the fact that only long axis views are possible with the ventromedian approach, M-Mode echo can not be used in birds to evaluate contractility and wall thickness. Therefore, measurements have to be taken on the 2-D-echocardiograph.

Longitudinal Vertical View ("Two Chamber View")

The vertical view shows the left ventricle and the left atrium (which is often not completely distinguishable from the surrounding tissue) as well as the left atrioventricular valve. Sometimes border areas of the right ventricle may also be seen next to the total reflexion of the sternum (Fig 12.4) but cannot be used for assessment. In this view, artifacts caused by reflexions of the sternal bone may produce a second "heart" lying outside the thoracoabdominal cavity (mirror picture artifact).

Longitudinal Horizontal View ("Four Chamber View")

In the four-chamber view, both ventricles, the interventricular septum, both atria, the atrioventricular valves and the aortic root with the aortic valves can be visualized (see Fig 12.4). In this view it is difficult to outline the borders of the atria.

Measurements in 2-D-echocardiography

Measurements have to be taken from 2-D images, since there is no possibility for a suitable cross section for M-Mode technique. Additionally, the images are of very small structures. Therefore the interpretation of measurements is limited and small changes in size may not be detected with the current techniques.

To measure specific cardiac parameters, the position of the transducer must be adjusted until the maximum expansion of the chamber is visible. Measuring points are demonstrated in Fig 12.3. All parameters should be measured in systole and diastole at the point of the widest distance using the inner edge method.⁵⁶ Measurements of the left ventricle are possible in both views, but are easier to obtain in the vertical view. In psittacines, there is a strong correlation between the sternal length/the body mass and the length of the left ventricle (IVL); the expected length can be estimated with the formula LVL = 0.5 + 0.33 x sternal length.³² Measuring the length of the right ventricle is more difficult because it is visible as an acute-angled triangle. Additionally, the muscular right atrioventricular valve is — due to its motility

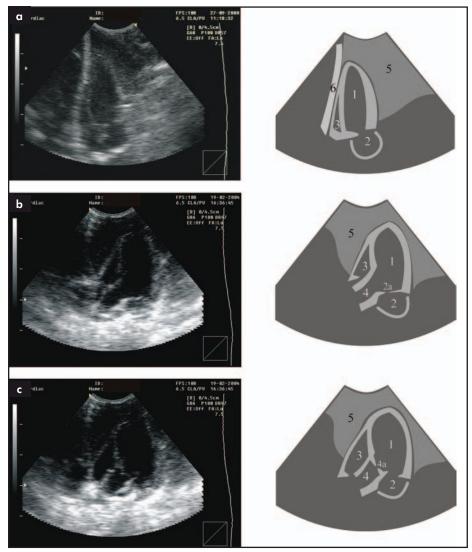

Fig 12.4 | Two dimensional echocardiography, normal hearts. a: vertical view, blue fronted Amazon (Amazona aestiva), b: horizontal view, systole, carrion crow (Corvus corone), c: horizontal view, diastole, carrion crow (Corvus corone). (1 = left ventricle, 2 = left atrium, 2a = left atrioventricular valves, 3 = right ventricle, 4 = aortic root, 4a = aortic valves, 5 = liver tissue, 6 = sternal reflexion).

— an imprecise margin for right ventricular measurement. The outer walls of the heart are often difficult to distinguish from the surrounding tissue. The thickness of the interventricular septum may give information about ventricular hypertrophy. Measurements of the atria are imprecise and therefore of limited use. The importance of atrial contraction for blood flow into the ventricles is limited, therefore assessment may not be important.⁴²

Calculations for Functional Assessment (Tables 12.1-12.3)

On the basis of the measurements obtained, the fractional shortening (FS) can be calculated. This is one functional parameter for evaluating the capability of ventricular contraction. It is calculated as the relative reduction of the width of the transverse left ventricular diameter during systole in relation to the diastolic diameter (%FS = (diastole - systole) 100/diastole). The values are different than those in mammals, which might be due to anatomical peculiarities (see above). Contractility of the right ventricle is significantly higher than the value found for the left one.

The relationship of the width of the ventricle to the length can give information about dilatation. For psittacines, a relatively constant value (systolic 0.33, diastolic 0.40) (see Table 12.3) has been noted. 32,33,34

Volume calculations, based on simplified models of the chamber volume of the left ventricle, have not yet been documented as diagnostic.³⁴

Preliminary reference values for morphometry and assessment of cardiac function have been established for psittacines, ^{32,33,34} birds of prey³ and pigeons¹⁵ (Tables 12.1-12.3).

Doppler-echocardiography

To date, there only a few reports of Doppler echocardiography in birds. The principles are the

same as in mammalian echocardiography, but specific problems exist. The frame rate when color Doppler mode is used is significantly lower in most ultrasound devices. This makes it difficult to assess blood flow. Also, pulsed-wave Doppler has limitations due to the high velocity of flow in the avian heart.

Color-Doppler can be used for the detection of valvular insufficiencies (reported in an Indian Hill Mynah Bird).³⁹ It is also helpful for the positioning of the gate for spectral Doppler-analysis to determine the degree of valvular insufficiency. In one case, the use of color Doppler for diagnosis of an aneurysm in a coronary artery has been reported.⁵² With the standard ventromedian approach, the diastolic inflow into the ventricles is displayed red (flowing towards the transducer) and the systolic outflow blue (flowing away from the scanner) (see Fig 12.5).

Spectral Doppler-echocardiography is the standard method for noninvasive blood flow velocity measurements in mammalian medicine. Signals are displayed as two-dimensional time versus velocity graphs. Two different types of spectral Doppler are of interest: pulsedwave (PW) and continuous-wave (CW). PW Doppler is limited to velocities lower than 2 m/second but allows measurements within an operator-specified sample volume or "gate". Diastolic inflow into the left and the right ventricle, as well as systolic aortic outflow, have been measured in psittacines and raptors using PW Doppler (Fig 12.6).5,43,47,49 For the mitral inflow, two peaks could be recorded (E-wave corresponding to ventricular filling, A-wave to atrial contraction); E:A was positive for macaws and African grey parrots, whereas in cockatoos it was negative.5 Blood flow within the pulmonary artery

could only be differentiated in a few cases.5 Measurements are given in Table 12.4.

CW Dopplers are useful for the detection of very high blood flow velocities but do not allow the measurement of the flow velocity at a certain point. No studies regarding the use of CW Dopplers in birds have been published so far.

Birds under stress significantly increase their intracardial blood flow velocity. It is recommended that Dopplerechocardiography be performed under anesthesia in these patients.

described technique for ante mortem diagnosis of cardiac diseases, it is used less frequently in birds compared to mammals. Difficulties may occur with the connection of the leads to the skin and stress may cause alterations of the recorded ECG. Additionally, no reference values have been published for many of the bird species.

The main indication for ECG is diagnosis and control of arrhythmias and conduction disorders. It may also be valuable for detecting enlargement of the ventricles and metabolic disorders. ECG can be used for monitoring cardiac function during anesthesia and for recording cardiac stages (systole, diastole) while performing other imaging techniques (eg, echocardiography). Another indication for performing ECG is monitoring cardiac disease therapy.

There are many reports on how to perform ECGs in birds. Some authors recommend examination under anesthesia, others prefer recording the ECG in the awake bird. Anesthesia may induce alterations in the ECG. With isoflurane anesthesia, arrhythmias have been described, such as second- and third degree AV-block, sinus arrest, T-wave depression and atrial premature contraction.¹

For the clinical application of an ECG in avian patients, six leads, as commonly performed in mammals, can be used. Due to the high cardiac heart rate, electrocardiographs in avian medicine must be able to run at a paper speed of at least 100 mm/second. Leads are attached on the right wing (RA), left wing (LA) and left leg (LL), and the right leg is connected to the ground (Lumeij and Ritchie, 1994). If the ECG is used to monitor anesthesia or to trigger echocardiographic images, bipolar leads (following the electrical heart axis; with one attached cranially to the sternum and slightly paramedian on the right side of the body, and the other one attached caudally to the sternum, slightly on the left side) may be sufficient.

Several techniques for attachment of the leads to the skin have been described (subcutaneous needles, alligator clips, specially constructed feather clips). In the authors' experience, alligator clips can be effectively used in birds, when clipped on the proximal part of the rachis of the feathers. By using alligator clips without sharp teeth there is no damage to the feathers. To get electrical contact with the skin, water soluble ECG gel or small amounts of alcohol are applied between the skin and clip.

The avian ECG is quite different from the mammalian ECG. A schematic lead II-ECG-complex typical for a healthy bird is shown in Fig 12.7. Reference values exist for racing pigeons,²¹ Amazons and African grey parrots²³ and some macaw species.⁶ A complete overview of the electrophysiologic evaluation of the avian heart and the clinical use of the ECG in birds is given by Lumeij and Ritchie.²²

POST MORTEM MORPHOMETRY

Whilst reproducible measurements of the thickness of the atrial myocardium are nearly impossible, the thickness of the ventricular myocardium is readily detectable. Due to the huge number of different species that are seen in avian practice, the establishment of reference values for each species is impossible. Fortunately, current investigations could prove that relative values (as a %) rather than absolute values (in mm) are of significance in the assessment of the avian myocardium.

Dissection of the heart under standardized conditions is a basic requirement for performing measurements of the ventricular myocardium thickness at necropsy. The heart should be placed on its left side on a cutting board. A longitudinal cut running through the apex of the heart, the uppermost region of the right ventricular wall and the center of the interventricular septum has to be performed. All blood clots must be removed and the mass of the heart should be determined. Measurements of the thickness of the myocardium at three regions of the left

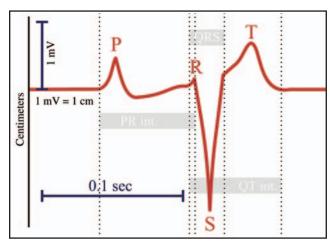

Fig 12.7 | Schematic view of a normal ECG-complex, lead II, in a healthy macaw. Measurement points following Lumeij.²²

and the right ventricular free wall as well as the interventricular septum should be made using precision callipers. Additionally, measurements of the length of the left ventricle should be ascertained (Fig 12.8).

To date, the amount of scientific data concerning the morphometry of the avian heart is limited. Scientific studies have been performed in two psittacine species (Melopsittacus undulatus, Alisterus scapularis) and the common buzzard (Buteo buteo). 44,45 Interestingly, by comparing the relative values (thickness of the myocardium in relation to the length of the sternum and the length of the left side of the interventricular septum, respectively) of these different species, it is speculated that the hearts of most avian species follow a set morphological pattern. The myocardium of the ventricles as well as the interventricular septum shows changes of the thickness from the base to the apex of the heart. Whilst the thickness of the left ventricular free wall decreases in the direction of the apex the interventricular septum and the right ventricular free wall become thicker from the base to the middle region and then decrease in thickness towards the apex (Fig 12.8 and Table 12.6).

Therapy of Cardiovascular Diseases

The therapy of avian cardiac disease is still in its infancy. Only a few scientific studies exist, and many drugs routinely used in mammals have not as yet been tested in caged and aviary birds. Overdosing may cause severe side effects; and the pharmacodynamics of drugs in birds is often different due to physiological differences.

Nevertheless, the principles of cardiac therapy are the same as in mammal medicine. Stabilization of the

patient is essential, and besides symptomatic therapy, the underlying disease has to be diagnosed and treated.

Because cardiac disease in birds is often not diagnosed until the heart decompensates, the veterinarian commonly has to deal with advanced changes. Due to weakness, emaciation and high-grade circulatory problems, these birds are often presented as emergencies. Stress during handling, examination and treatment may be fatal

ACCOMPANYING THERAPY

Accompanying therapy is essential to maintain circulatory stability and organ function. Liver and kidney function may be affected by circulatory problems. The liver may be congested, renal blood flow may be reduced, and the resulting increase of toxic metabolites and urinary excreted substances may affect the general condition of the bird. The function of the lung can be reduced as a direct result from left heart failure causing pulmonary congestion. Fibrotic lungs will increase the work load of the right ventricle. In addition, reduced air

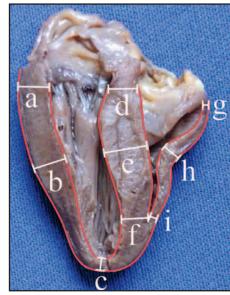

Fig 12.8 | Heart of a common buzzard (Buteo buteo). Illustration of the measuring points for the post-mortem evaluation of the myocardial thickness: a to c = left ventricular free wall, a = basal, b = middle, c = apical; d to f = interventricular septum, d = basal, e = middle, f = apical; g to i = right ventricular free wall, g = basal, h = middle, i = apical; distance d to c = length of the left ventricle close to the interventricular septum.

sac volume can lead to dyspnea and hypoxemia damaging the heart.

Cardiac therapy's goals are to reduce congestion (diuretics, ACE inhibitors) and improve cardiac output (ACE inhibitors) which can improve renal/hepatic function. The following supportive measures should also be taken:

- Incubation in a warm environment (80° F (25° C) or above), with sufficient air humidity (60% relative humidity or above) in order to improve circulation and to reduce energy loss.
- Reduction of stress: handling should be reduced to a minimum. Positioning of the patient in ventrodorsal recumbency (eg, for radiology) is a risk and should be considered carefully. Diagnostic procedures in an upright position should be performed (eg, echocardiography). The environment should be calm and temporarily darkened.
- Fluid administration is essential to prevent circulatory collapse and shock and to prevent dehydration due to increased diuresis due to therapy with ACE-inhibitors, and furosemide. Therapy should be

started intravenously or via intraosseus canula. Maintenance administration may be subcutaneous or (preferably) orally. Careful monitoring must be done so the patient is not volume overloaded which would increase congestion.

- Addition of electrolytes, vitamins, amino acids and buffer solution may also be indicated.
- Fluid aspiration from the thoracoabdominal cavity is easily performed in avian patients (if possible, do it ultrasound-guided) and helps to reduce dyspnea due to ascites. For pericardiocentesis, see pericardial effusion.

DRUGS FOR CARDIAC THERAPY (see Table 12.7)

Heart Glycosides (Digoxin)

Heart glycosides have a positive inotropic effect on the contraction of cardiac muscle. Also relaxation of cardiac muscle will be improved and the heart rate will decrease. These effects lead to a reduction of oxygen demand and an improvement in circulation of the cardiac vessels. Therefore digoxin works best for cardiac diseases that involve volume overloads (insufficient valves), decreased contractility (dilatative cardiomyopathy), or supraventricular tachycardia. The increased cardiac function decreases ascites and edema. To date, there are only two scientific studies on the use of glycosides in pet birds. Pharmacokinetics of digoxin has been examined in sparrows (*Passer domesticus*), budgerigars (*Melopsittacus undulatus*), and quaker (*Myiopsitta monachus*). ^{11,54}

The therapeutic margin of cardiac glycosides is small, and half-life varies greatly between species. Overdosing may lead to accumulation of cardiac glycosides, and side effects include arrythmias. Contraindications are ventricular tachycardia, second and third degree atrioventricular heart block, hypercalcemia, potassium deficiency and stenotic valves. Cardiac side effects are documented with the combination of glycosides and ketoconazole (therapy of aspergillosis) in humans.

In the authors' experience, cardiac glycosides are useful for emergencies. Chronic administration may be problematic due to difficulties in controlling the side effects and plasma levels. An initial recommended dose of digoxin is 0.02 to 0.05 mg/kg (20 to 50 μ g/kg) q 12 h. Maintenance should be dosed carefully at 0.01 mg/kg (10 μ g/kg) q 12 h. $^{11.54}$

Angiotensin Converting Enzymes (ACE-) Inhibitors (Enalapril)

Angiotensin II is responsible for the constriction of arterial and venous vessels and the retention of sodium and water by the kidneys. The inhibition of this hormone

leads to diuresis (and indirectly to an improvement of renal function), and a decrease of blood pressure. The effect on the heart is a decreased pre- and afterload so that cardiac workload is eased and the cardiac muscle cells may be able to recover.

Although scientific studies regarding the pharmacokinetics of enalapril in birds are lacking, clinical experiences with this drug exist. The results indicate that its use in birds with cardiovascular disease may be beneficial. Empirical dosage used for treatment of birds is 5 mg/kg/day, with reduction to 1 mg/kg/day following improvement of cardiac function. Tolerance is much better when compared to cardiac glycosides and long term administration is possible. Observed side effects after high-dose therapy (5 mg/kg/day) were an increase of PCV and signs of dehydration. These effects were not present when the dose was reduced to 1 mg/kg BID orally.^{29,47}

Diuretics (Furosemide)

Indications for furosemide are pulmonary edema, ascites, and pericardial effusion as well as an increased pre- and afterload. The recommended dosage used in birds is 0.15 to 2.0 mg/kg/day PO/IM.³⁶ Long term administration may lead to a potassium deficiency and therefore cause heart arrhythmias. Since there is a risk of dehydration, especially in small birds, additional careful fluid administration is essential.

In the authors' experience, the main use for diuretics is in the initial therapy of cardiac failure with fluid accumulation (ascites, pericardial effusion) in combination with ACE-inhibitors or glycosides.

Antiarrhythmics (B-blockers)

A protective effect against the development of atherosclerotic plaques has been demonstrated using oxprenolol in poultry (2 mg/kg/day).²⁷ Other uses, such as for supraventricular or ventricular arrhythmias, have not been described.

Before using antiarrhythmics, it is important to exclude metabolic causes for the arrhythmia (eg, potassium deficiency, see diuretics). The safety margin of these drugs is small, and the half-life is normally very short, but the clinical effects can last longer, especially if cardiac failure is present.

Calcium Sensitizers (Pimobendan)

Calcium sensitizers are substances with a positive inotropic effect. The pharmacokinetic mechanism is unknown and there are no scientific reports of the use of calcium sensitizers in birds.

Table 12.7 | Cardiac Medications in Birds*

Drug	Indication	Application / Dose	Remarks / Side effects
Digoxin	Systolic myocardial failure	PO 0.02-0.05 mg/kg BM BID initially, following 0.01 mg/kg BM BID	Low therapeutic index Overdosing: bradycardia, arrhythmia, diarrhea, vomitus
Enalapril	Myocardial failure, increased pre-/afterload	PO 2.5 mg/kg BM BID initially, after one week 1 mg/kg BM BID	High therapeutic index Side effect: dehydration
Furosemide	Pericardial effusion, edema, increased pre-/afterload	PO, IM 0.15-2.0 mg/kg BM SID/BID	Risk of dehydration esp. in smaller birds (lorikeets) Side effect: arrhythmia caused by potassium deficiency
Oxprenolol	Cardioprotection, prevention from arteriosclerotic plaques (poultry)	PO 2 mg/kg BM SID	Possible side effects: hypotonia, arrhythmia, tachycardia, AV-block
g-Strophantin (only available in EU)	Circulatory system stimulant	PO drop-wise, to effect IV, IM 1 ml/kg BM	In case of long-time overdosage, heart hypertrophy especially in smaller birds possible
Atropine	Conduction disturbances, bradycardia	IM 0.01-0.1 mg/kg BM SID	Only short-time Overdosing: arrhythmia, gastrointestinal stasis
Etilefrine (only available in EU)	Hypotonia	PO drop-wise, to effect	Possible side effects: tachycardia, arrhythmia, hypertonia

*Hamlin and Stalnaker;¹¹ Wilson;⁵⁴ Lumeij and Ritchie;²² Ritchie and Harrison;³⁶ Pees;²⁹ Krautwald-Junghanns and Kummerfeld.¹⁹ SID = 1x/day, BID = 2x/day, PO = orally, IM = intramuscular, BM = body mass

Pathology of Cardiovascular Diseases

Caged birds, in comparison with free living birds, are frequently compromised by restricted exercise, nutritional deficiencies and abnormal climactic conditions. Combined with the bird's natural physiologically high blood pressure, the risk factor for cardiovascular disease in pet birds is significant.

Recent post mortem studies show the frequency of cardiac pathology in pet birds. According to these studies, heart disease occurs commonly in avian species.

Oglesbee and Oglesbee²⁴ found gross and histological evidence for cardiac disease in 26 of 269 psittacine birds. A study of 107 psittacines submitted for routine necropsy found macroscopic lesions of the heart and/or the large vessels in more than one third of the birds^{4,20,42} (Table 12.8). In 99% of these 107 birds, at least low-grade histologic changes were present (predominantly inflammatory mixed-cellular infiltration, bacterial infiltration, and/or fat cell accumulation within the myocardium).

Diseases of the heart may occur as the result of congenital, infectious, toxic or idiopathic etiologies. No data currently exist on age-related cardiovascular diseases in pet birds. A variety of cardiac abnormalities occur secondarily as acquired disease and/or compensation/decompensation due to other organ failure (ie, lung and liver), neoplasia or systemic infections. 16,17,20

CAUSES OF (CONGESTIVE) HEART FAILURE

Heart failure is the clinical syndrome resulting from abnormalities of cardiac function (eg, myocardial failure, valvular regurgitation).

Table 12.8 | Incidence of Selected Cardiac and Vascular Diseases in 107 Psittacine Birds. Macroscopic Findings (Findings in 39 Birds (36.4 %)*

	Findings	Cases
Pericardium	Pericarditis	16 (14.9%)
	Pericardial effusion	6 (5.6%)
Myocardium	Hypertrophy/dilatation	16 (14.9%)
	Petechial bleeding	6 (5.6%)
Endocardium	Endocarditis valvularis	1 (0.9%)
Aorta/A. pulmonalis	Yellow discoloration/hardening	11 (10.3%)

*Braun; 4 Krautwald-Junghanns20

The syndrome "congestive heart failure (CHF)" results from inadequate cardiac output and an increased preload. Fluid retention is caused by elevated venous and capillary pressures. In left heart failure, an increase of the pressure in the left atrium and the pulmonary veins leads to pulmonary edema. In birds with right heart failure, ascites, liver congestion and hydropericardium are commonly seen.

CONGENITAL DISEASES

Due to the high physiological load of the avian heart, congenital cardiovascular disorders often lead to early embryonic or fledgling death. They are rarely presented as clinical diseases in birds, ante mortem diagnosis is rare and the cause is normally found only at necropsy. In one case, evidence for a congenital defect of the muscular right atrioventricular valve could be found in a 35-year-old Amazon diagnosed with dilatation of the right ventricle.³⁰

PERICARDIAL DISEASES (PERICAR-DITIS, PERICARDIAL EFFUSION)

Pericardial changes frequently found in birds include inflammation (pericarditis) and effusion (hydropericardium, hemopericardium).

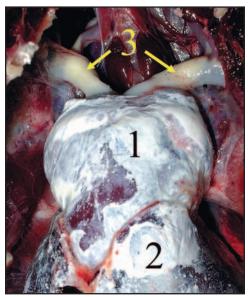

Fig 12.9 | Necropsy, blue fronted Amazon (Amazona aestiva aestiva), pericarditis urica. Uric acid deposits can be seen on pericardium (1) that covers the heart and the serosa of the liver (2). The yellowish discoloration of the large vessels (3) is an indication for arteriosclerosis.

Fig 12.10 | Radiograph, ventrodorsal view, African grey parrot (Psittacus erithacus), tentative diagnosis of cardiac disease (corresponding to Fig 12.11). The heart (1) and the liver (2) shadow are enlarged. Detail recognition in the thoracoabdominal cavity is reduced; the air sacs (3) are compressed.

Inflammation of the pericardium may develop in the process of infectious diseases of surrounding tissue. Common causes are generalized trichomonas infections in pigeons, mycotic infections originating from the respiratory tract, and bacterial infections including mycobacteriosis. Deposits of uric acid in the pericardium may be seen with visceral gout (Fig 12.9).

Hydropericardium is the cardiac change most frequently diagnosed ante mortem. It may develop with infectious exudative pericarditis, but can also occur due to congestion in cardiac failure, metabolic disorders (protein deficiency) or as an idiopathic syndrome. Hemopericardium is generally found following trauma or sclerosis with subsequent rupture of vessels, and is almost always fatal.

Clinical symptoms in birds with pericarditis are often nonspecific. Diagnosis is usually confirmed at necropsy. Radiography may reveal cardiomegaly with an irregular cardiac silhouette. Echocardiography is of limited use for diagnosis if there is no pericardial effusion. Endoscopy is the most reliable ante mortem diagnostic aid, although there is an increased risk during anaesthesia (see Chapter 24, Diagnostic Value of Endoscopy and Biopsy). In cases of acute visceral gout, plasma uric acid levels may be increased.

Common symptoms in birds with pericardial effusion are abdominal distension, dyspnea and exercise intolerance. Hydropericardium is often combined with congestion of the liver and ascites. The typical radiographic

findings are enlargement of the heart and liver shadow as well as loss of detail (Fig 12.10). ECG may show low voltage,²² but allows only a tentative diagnosis (adipose tissue and space-requiring processes like tumors can cause low voltage on the ECG as well).29 The only reliable ante mortem diagnostic test for pericardial effusion is echocardiography. Hydropericardium can be visualized as an anechoic area between the myocardium and the pericardium (Fig 12.11). For further examinations (cytology, microbiology) an ultrasound guided aspirate from the pericardial space may be taken. In most cases, pericardial effusion is non-infectious and clear. Nevertheless, inflammatory cells may indicate infection, and culture may help to identify bacterial or fungal causes.

Treatment of exudative pericarditis, in addition to treating the underlying condition, may include administration of furosemide or another diuretic. Treatment for visceral gout is generally unrewarding (see Chapter 16, Evaluating and Treating the Kidneys). For treatment of hydropericardium due to congestive heart failure, diuretics in combination with ACE inhibitors are indicated.29,47 Pericardial effusion may result in diastolic heart failure, ie, in an insufficient filling of the ventricles in diastole due to compression of the atria by the fluid in the pericardial cavity. This is a contraindication for the use of glycosides. An ultrasound guided pericardiocentesis may be performed to remove fluid from the pericardial space. Repeated echocardiography can be used to evaluate success of the therapy.

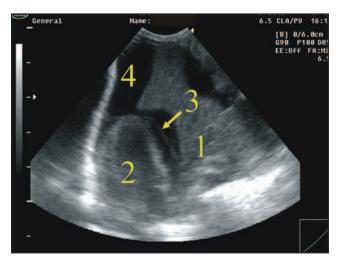

Fig 12.11 | 2-D-Echocardiography, African grey parrot (*Psittacus* erithacus), pericardial effusion and ascites (4) (corresponding to Fig 12.10). The pericardial effusion (1) can be seen as an anechoic area between the heart (2) and the pericardium (3).

MYOCARDIAL DISEASES (MYOCARDIAL FAILURE)

A decreased myocardial contractility (myocardial failure) may be primary, idiopathic (dilatative cardiomyopathy), or secondary, as a result of systemic diseases of infectious (myocarditis), toxic, metabolic (lipomatosis cordis, arteriosclerosis) and neoplastic origin. Frequently, an increased workload (eg, due to arteriosclerosis and pulmonary hypertension) leads to hypertrophy of the ventricles and can eventually result in decompensation and dilatation. Valvular insufficiencies can also lead to ventricular dilatation and eventually failure.30 In psittacines, myocarditis is described as a complication in neuropathic proventricular dilatation disease. 40,51 Iron deposition in the myocardium combined with dilatation of the ventricles occurs in mynah birds with iron storage disease.9 After prolonged transport of wild birds, myocardial necrosis may be seen as neurogenic arrhythmias as a consequence of metabolic disturbances.

Mostly myocardial failure is right-sided. Systemic lung diseases (ie, chronic mycosis) frequently result in dilatation of the right ventricle (including the right, muscular AV valve) and the right atrium and therefore the venous part of the circulatory system. Isolated left-sided myocardial failure is rare, since the resulting pulmonary congestion also affects the right ventricle and leads to a secondarily increased afterload and eventually right-sided CHF.

Although one case report suggests that myocardial compensation of valvular insufficiencies may occur for years, decompensation and development of clinical signs seem to develop more quickly in birds than they do in mammals.³⁰

Clinical signs of myocardial failure of any cause can pres-

ent as generalized weakness and as respiratory impairment. Hepatic congestion and ascites often cause abdominal distension.

Radiographs may demonstrate a consolidated, enlarged and sharply delineated shadow of the entire heart and liver. The appearance of the lung fields may demonstrate homogenous or non-homogenous increased opacity of the honeycomb pattern of the lungs which indicates pulmonary edema.

In birds with dilatative cardiomyopathy, the ECG may show an increased R-wave and a negative P-wave. The heart axis can change to between 0° and -170°. Arrhythmias are often seen with cardiomyopathy and myocarditis.²²

In 2-D echocardiography, altered wall thicknesses and diameters of the ventricles as well as decreased contractility can be seen (measurements see Tables 12.1-12.3). In birds with right heart failure, the right ventricle is often as large as the left (Fig 12.12). Accompanying common findings are hydropericardium, ascites and congested liver parenchyma (see diluted vessels, Fig 12.13).

In case of suspected cardiomyopathy, blood-chemistry evaluation should include AST, CK, uric acid, LDH and electrolytes.

In addition to treatment of the underlying cardiac disease, supportive care including cage rest and diet change is important. Diuretics are indicated when edema (eg, pulmonary edema) or ascites are present. In the authors' experience, a combination of glycosides, ACE-inhibitors and diuretics seems to be the most effective initial therapy for cases of acute heart failure. For long-term therapy, ACE-inhibitors are preferable.^{29,47}

ENDOCARDIAL DISEASES (ENDO-CARDITIS, VALVULAR INSUFFI-CIENCY, VALVULAR STENOSIS)

Alterations of the endocardium, in particular the valves, may be idiopathic.³⁰ However, these changes are found more frequently secondary to infections with streptococci, staphylococci, *Pasteurella multocida* or *E. colt.*^{20,22,35}

Independent of the etiology, functional damage of the AV valves leads to regurgitation and to left heart failure with pulmonary edema (small circulatory cycle) and/or right heart disease with liver congestion (large circulatory cycle) and can cause general cardiac failure. Thickening of the right AV valve is normally caused by muscular hypertrophy. It may be a consequence of valvular insufficiency or due to hypertrophy of the whole right ventricle (see Fig 12.12). This alteration occurs

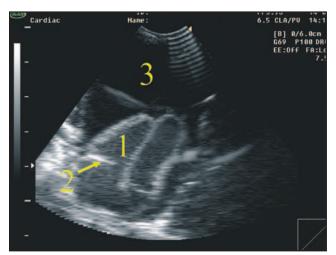

Fig 12.12 | 2-D-Echocardiography, yellow-crowned Amazon (Amazona ochrocephala), right heart failure. The right ventricle (1) is as large as the left one, the muscular right atrioventricular valve (2) is clearly thickened (3 = ascites).

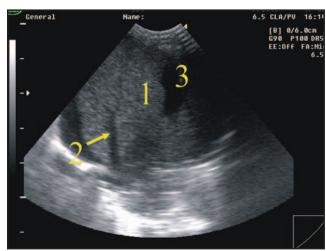

Fig 12.13 | 2-D-Echocardiography, African grey parrot (Psittacus erithacus). Liver (1) congestion and ascites (3). Dilated vessels (2) can be demonstrated in the liver tissue.

more often than alterations of the left AV valve. Chronic inflammation of the semilunar valves can also result in stenosis.20

Clinically, nonspecific symptoms (weakness, dyspnea, distended abdomen) may be noticed.

Radiographic investigation gives information about cardiac size and congestion of organs (see Myocardial Diseases section) but radiographic diagnosis of endocardial alterations is not possible.

2-D-Echocardiography can show accompanying myocardial thickening and changes of the valves, especially thickening of the right atrioventricular valve (see Fig 12.12).30,35 Doppler echocardiography is the imaging tool of choice for demonstration of valvular regurgitation in mammals. Although initial examinations have been performed in birds (see Echocardiography), little has been published about the use of Doppler echocardiography in case of suspected valvular damage. In an Indian hill mynah, color flow and spectral Doppler have been used for demonstration of mitral regurgitation.^{37,39}

A good prognosis may be given in cases of acute endocarditis with aggressive treatment of the causal agent (Myocardial Diseases section).

In patients with valvular regurgitation, glycosides can be used, whereas in case of stenosis, these drugs are contraindicated. A decrease in the heart rate to a normal range and decreased congestion may be interpreted as therapeutic success.

ARTERIOSCLEROSIS

Arteriosclerosis is the most frequently described pathologic change of the vessels in psittacine birds. 4,10 Different

etiological factors are discussed; the most frequent causes are hyperlipidemia, endothelial inflammation, toxins, immune complexes, hypertonia and/or stress factors. Age and nutritional deficiencies over many years, as well as lack of exercise seem to play a role in the development of arteriosclerosis. 13 Psittacines commonly affected by arteriosclerosis are amazons (especially blue fronted Amazons), African grey parrots and cockatoos. 4,13,20

Macroscopic changes include arterial wall thickening, intimal roughening, induration and yellowish discoloration.¹⁰ Calcification can cause plaque-like or diffuse hardening of the larger arteries like the aorta and brachiocephalic trunk (Fig 12.14). Arteriosclerosis cannot be diagnosed by gross findings alone, but requires histological examination, especially in earlier stages. 10,20

A diagnosis of arteriosclerosis is often made at necropsy. Clinical findings are usually absent or may only lead to a tentative diagnosis. Possible symptoms include lethargy, neurological signs (tremor, paralysis of the legs), decreased exercise tolerance and dyspnea.8,13,14 Acute death may occur.

Radiologically, an increased radiodensity and widening of the aorta may be seen in advanced cases, sometimes in connection with left atrial or left ventricular enlargement. Echocardiography may be useful for diagnosis of the arteriosclerotic processes of the large vessels close to the heart, but no systematic studies have been done to date. In a white cockatoo, an aneurysm of a coronary artery associated with arteriosclerosis has been diagnosed by echocardiography.52

Effective therapy for arteriosclerosis is not known for birds. In poultry, ß-blockers (eg, oxprenolol) proved to have a protective effect against the development of

arteriosclerotic plaques. Unfortunately it is not possible to remove plaques which are already present.^{27,28} Diuretics may be indicated as well as ACE-inhibitors if heart failure occurs.⁷ Balanced food supply and sufficient opportunities to exercise are important preventive factors. Proper flight exercise and diet will prevent obesity, a major contributor to this cardiac disease.

CIRCULATORY DISTURBANCES (CIRCULATORY COLLAPSE, SHOCK)

Physiologically, the avian circulatory system has a large load capacity. Unexpected deaths, after catching small birds, can sometimes be attributed to asphyxia (strong pressure on the sternum). Long restraint of fractious birds may lead to circulatory collapse, especially in birds with dyspnea, ascites (resulting in displacement of the air sacs) or cardiac failure. Hypovolemic, septic (toxic-infectious) and neurogenic shock as well as anaesthetic complications may also be a cause. Overcrowding of carriers or transporting in temperatures near or above 100° F (38° C) may lead to circulatory collapse.

Clinical symptoms of circulatory collapse start as respiratory signs with spread wings/ legs and tachypnea/ dyspnea. This is followed rapidly by respiratory arrest, convulsions with opisthotonus, and a loss of consciousness.

Further diagnostics should only be done after stabilization of the patient. If possible, the bird should be kept upright for examination (eg, circulatory risk during positioning for radiology). The treatment for shock is always handled as an emergency situation. The bird must immediately be brought to a calm and darkened area. A volume substitution with warmed (100-103° F) lactated

Fig 12.14 | Necropsy, African grey parrot (*Psittacus* erithacus), with arteriosclerosis. Thickening and discoloration of the wall of the large vessels (arrows).

Ringer's solution (LRS) or half-strength LRS + 2.5% dextrose (IV, intraosseus cannula, for maintenance also SC) is indicated. Infusions with sodium bicarbonate solution should be given in case of metabolic acidosis, recommended dosage is 1 mEq/kg (=1 ml/kg), in intervals of 15 to 30 minutes up to a maximum of 4 mEq/kg.⁵⁵ Additionally, oxygen supply is indicated. If faced with respiratory arrest administration of doxapram (respiratory stimulant, orally dropwise to effect) may be useful. Oral /IV/IM administration of g-strophantin (see Table 12.7) may successfully stabilize patients presenting in circulatory failure. Sympathomimetics (etilifrine) may be administered orally to increase the stroke volume in case of heart failure (in particular, in case of cardiogenic shock).

Fig 13.1a | Mustached parakeet with facial dermatitis resulting in feather loss and replacement. Pin feathers predominate in the affected area.

Fig 13.1b | A burn from administrating scalding hot food. Microwaved food is often the source.

Skin and feather problems are common disorders in pet avian species (Fig 13.1a). The skin has limited responses to insults. A variety of causes will lead to similar clinical signs and possibly similar gross and histologic changes. The clinician's challenge is to use available diagnostic methods to determine an etiology and rational therapeutic approach.

Birds often present with feather loss or picking. The appearance of the skin may vary from grossly normal to severely inflamed and/or necrotic (Fig 13.1b). In assessing gross morphologic changes, the effect of self-trauma must be considered. Although the lesions may be due to a primary problem within the skin and/or feathers, a variety of internal disorders, as well as behavioral problems, can also result in external lesions.

History

Arriving at a meaningful diagnosis requires a logical process that considers the differential diagnostic possibilities. History is essential. A complete history should include information on the bird's environment, changes in routine and diet. (See Chapter 4, Nutritional Considerations and Chapter 6, Maximizing Information from the Physical Examination for more specific information).

A description of the physical surroundings of the bird is needed, including such things as temperature and humidity, which can influence normal molting and which may play a part in clinical disease syndromes. The conditions of other birds in the household/aviary should also be determined. References are available for feather anatomy review.⁶

Physical Examination

Refer to Chapter 6, Maximizing Information from the Physical Examination for the description of a complete physical examination. During the physical examination, specific dermatologic lesions should be examined and classified. Examination includes the distribution of lesions, presence or absence of pruritus, relative conditions of the skin and feathers and presence of plaques, ulcers and exudates. The association of individual lesions with specific conditions is not as well documented in birds as it is in domestic pets. Notation of these dermatologic abnormalities will aid in both the clinical description to accompany biopsy submissions and in tracking by the practitioner of the course of the disease. A simple anatomic illustration, such as is used in dog and cat medicine can be valuable in recording these lesions. See Chapter 6, Maximizing Information from the Physical Examination for an example of this stamp.

DIAGNOSTICS

Evaluation of systemic illness and organ function via a complete blood count (see Chapter 22, Diagnostic Value of Hematology) and serum biochemistries (see Chapter 23, Diagnostic Value of Biochemistry) should be performed. Specific tests for syndromes such as PBFD circovirus may be indicated (see Chapter 32, Implications of Viruses in Clinical Disorders). An evaluation for nutritional deficiency or toxicities should be made from the dietary history (see Chapters 4, Nutritional Considerations and Chapter 6, Maximizing Information from the Physical Examination).

Several diagnostic procedures are available in order to gain information about skin lesions (Tables 13.1, 13.2). Scrapings may reveal the presence of mites, but in some lesions the mites are deep within the subcutis and will be missed by superficial scraping. Impression smears can give an indication of inflammation vs. neoplasia. Bacteria and fungi are also seen in impression smears, but their significance may be difficult to determine. Feather pulp smears potentially provide information concerning inflammatory processes within the pulp. Care must be taken not to confuse melanin granules with bacteria. Melanin granules will be uniform with tapered ends and will not be stained, having a natural brown-black color.

Culture is important but must be done correctly or the significance of the isolate is questionable. If folliculitis is suspected, aspiration of the follicle by sterile needle and syringe is necessary.

Skin and feather biopsy is an important tool, but its effectiveness is compromised by the lack of clinical history and description in many submissions. The presence

Table 13.1 | Diagnostics for Avian Skin Lesions

Table 13.2 | Therapy Pending Diagnostic Results

Clinical Presentations	Therapy
Feather loss or skin abnormality with no self-trauma	Dietary assessment and correction Environmental assessment and correction Preliminary therapy based on Gram's stain results, if applicable Viral profiling with supportive care
Pruritus	Topical therapy (see Chapter 9, Therapeutic Agents) Systemic antipruritic/tricyclic antidepressant (eg, diphenhydramine, amitriptyline, see Chapter 9, Therapeutic Agents) Dietary assessment and correction Environmental assessment and correction Preliminary therapy based on Gram's stain results, if applicable Behavior consultation
Self-mutilation	Barrier to mutilation (Elizabethan collar or modified extension collar) Antibiotics for systemic infection Topical antibiotic/antifungal (eg, 1% silver sulfadiazine cream ^a) Preliminary therapy based on Gram's stain results, if applicable Consider psychotropic medications (see Chapter 3, Concepts in Behavior and Chapter 9, Therapeutic Agents) Behavior consultation

of an overwhelming microbial population can be diagnostic, although the sensitivity of the organism to various antimicrobials cannot be determined from histopathology. In the absence of a definitive etiologic agent, allergy, self-trauma or endocrinopathy may be suggested from the biopsy.

Pulling of feathers and submission for histopathology may lead to a diagnosis in some cases, but if the feathers are normal the possibility of primary skin disease cannot be ruled out.

Because skin disease can reflect internal disease, appropriate laboratory tests or radiographic examination may be indicated in cases where a thorough examination has ruled out primary disease of the skin or feathers. (See Chapter 15, Evaluating and Treating the Liver and Chapter 4, Nutritional Considerations).

Congenital and Acquired Malformations

Occasional feather cysts are seen in all species. In some

Fig 13.2 | Feather cyst containing concentrically laminated keratin that must be differentiated from caseous exudate.

canaries there is an apparent inherited predisposition that is associated with color. Neoplasia has recently been found in the formation of feather follicle cysts in canaries.

Grossly, feather cysts present as an oval or elongated swelling of the feather follicle with accumulation of yellow-white material (keratin) (Fig 13.2). The gross lesions must be differentiated from follicular infections. The causes of acquired feather cyst formation are usually not determined but can include infection, trauma or any condition that interferes with normal growth of the implicated feather.

Resection of a feather follicle cyst is indicated in the presence of self-trauma or recurrent infection. (See Chapter 35, Surgical Resolution of Soft Tissue Disorders for this procedure).

Congenital or developmental beak abnormalities are encountered with some frequency. Improper incubation or feeding techniques have been implicated but have not been documented as causative. The two most common presentations are mandibular prognathism and scissors beak. (See Chapter 14, Evaluating and Treating the Gastro-intestinal System for correction of beak deformities).

Abnormalities of the beak or claws can be a reflection of abnormalities of the underlying bone. They can also result from trauma, infection or neoplasia interfering with growth of the germinal epithelium of the beak or claw keratin. The result can be asynchronous growth or incomplete keratinization. Vitamin deficiencies that cause problems in domestic poultry are not well documented in pet avian species. Hepatopathy has been linked to beak and nail deformities in psittacines, but whether this is a direct result of the hepatic insufficiency or a sequela to nutritional disease is not well documented.

See Chapter 6, Maximizing Information from the Physical Examination and Chapter 15, Evaluating and Treating the Liver for photos of feather, beak and nail deformities.

Infectious Diseases

PARASITIC

The primary parasitic skin disease is mite infestation. Several different types of mites are found affecting both feathered and unfeathered skin. Most of these parasites are present in the superficial portion of the skin, which is usually hyperkeratotic and acanthotic, leading to gross thickening, irregularity and flaking. Severe and/or chronic infestation of the cere can result in malformation of the beak (Fig 13.3a).

Mites are usually superficial and can be demonstrated by skin scraping. Some species of mite and some individual cases will require deep scrapings or biopsy to identify.

Knemidocoptes spp. is most prevalent in budgerigars and passerines. The presentation in budgerigars is usually a pronounced hyperkeratosis of the cere and adjacent tissue. Occasionally the vent and legs of budgerigars will be affected (Fig 13.3b). A fine pinhole appearance of affected tissue on the cere is typical with this mite infestation. Clinical disease seems to require some degree of immune compromise.

Passerines with *Knemidocoptes* spp. generally present with "tassel foot." This hyperkeratosis of the legs is often accompanied in chronic cases with a curling and overgrowth of the nails.

Ivermectin has been utilized topically, orally and via injection for the treatment of mites, including *Knemidocoptes* spp. (See Chapter 9, Therapeutic Agents). In budgerigars that are otherwise clinically healthy, the infestation commonly clears, although recurrence is possible. Passerines with *Knemidocoptes* spp. infestation often improve but may not clear with ivermectin therapy. This may be due to secondary staphylococcal or mycotic infections.

Lice are uncommon in well cared for pet birds. See Chapter 6, Maximizing Information from the Physical Examination for photos. Unless the infestation is severe, gross lesions are not seen. Treatment with ivermectin is generally effective, although pyrethrin and carbaryl powders are also used successfully.

MYCOTIC

Folliculitis due to dermatophytes appears to be less common in birds than its counterpart in mammals, based on biopsy material. When present, there may be gross swelling of follicles with variable hyperkeratosis and crust formation (Fig 13.4). A variable amount of necrotic debris may be seen.

Fig 13.3a | Roughened, inflamed cere and face due to *Knemidocoptes* spp. mite infestation.

Fig 13.3b | A close up view of a *Knemidocoptes* spp. mite infestation showing the characteristic pin-point tunnels in the skin that can be used to make the diagnosis.

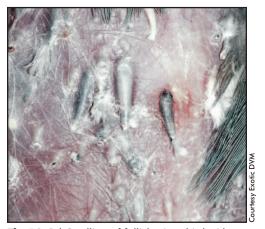

Fig 13.4 | Swelling of follicles in a bird with dermatomycosis.

Fig 13.5 | Amazon with Malassezia spp. facial dermatitis.

Recent research indicates that *Malassezia* spp., *Aspergillus* spp. and other fungi may play a role in some cases of dermatitis or feather picking. Clinical reports of improvement in feather plucking following nebulization with antifungal agents for respiratory disease lend credence to this possibility. (M. Stanford, personal communication, August, 2001). Further research is needed to determine whether fungal infection or sensitivity to *Aspergillus* spp. may play a role in dermatitis and feather picking.

Malassezia spp. is occasionally found as an etiologic agent, generally documented on cytology or histopathology, for feather loss and dermatitis. Treatment is largely anecdotal and follows the sensitivities of this organism noted in other species. Oral fluconazole and topical clotrimazole or chlorhexidine spray have been used with good results. This may be an under-reported syndrome related to feather destructive behavior (Fig 13.5).

Saprophytic fungi have been noted to cause black discoloration of feathers in birds. The prevalence of this type of fungal growth is unknown but it seems most likely to occur in birds with marginal hygiene and/or health.

BACTERIAL

Two primary forms of bacterial skin disease are commonly seen. Folliculitis is often associated with *Staphylococcus* spp. Grossly there is swelling of the perifollicular skin with a variable amount of reddening. The lesion must be differentiated from mycotic folliculitis.

Generalized bacterial dermatitis (pyoderma) is usually intensely pruritic leading to self trauma that results in a more severe superficial lesion. Reddening, exudation and crust formation are associated with necrosis (Fig 13.6). The necrosis may extend through the epidermis into the dermis in severe cases. Bacteria, usually grampositive cocci, may or may not be present in samples taken for microscopic examination.

Long-term antibiotic therapy is often needed in these cases. A positive culture and sensitivity will allow the selection of the appropriate antibiotic. A Gram's stain performed at the time of culture may improve interpretation of the culture results. In the absence of a positive culture, treatment may be selected based on the common sensitivities of the class of organisms identified in

Fig 13.6 | Generalized bacterial dermatitis leading to necrosis, reddening and crust formation.

Fig 13.7 | Localized periocular inflammation and minimal feather loss in a lovebird with circovirus infection.

the Gram's stain. Treatment failures are often the result of either continued self-trauma or insufficient length of antibiotic therapy.

A specialized form of bacterial dermatitis is severe chronic-active pododermatitis. (See Bumblefoot/Pododermatitis under Non-Infectious Diseases).

Focal granulomatous dermatitis due to mycobacterial infection is also seen. Clinically, the lesion presents as a lump or multiple lumps that histologically are comprised of large macrophages and a variable number of heterophils and plasma cells. Acid-fast bacteria are found in the macrophages.

VIRAL

Circovirus

Psittacine beak and feather disease virus (PBFDV) is one of several avian circoviruses. This virus is enzootic in many species of free-ranging Australian parrots and has also been found in free-ranging African parrots.

PBFDV in nestlings is acute in onset and generalized so that it affects all growing feathers. Acutely affected birds may die within 2 months of the onset of disease. The chronic form of disease is generally seen in older birds when these birds go through their first molt. Dystrophic feathers replace normal ones during the molt. Powderdown feathers may be the first affected in cockatoos (*Cacatua* spp.).

Currently, PBFDV in the United States is most commonly seen in lovebirds (*Agapornis* spp.), budgerigars, lories, lorikeets, *Eclectus* spp. and African grey parrots (*Psittacus erythacus*). Feather lesions in lovebirds are usually not as severe as in cockatoos and may be localized (Fig 13.7). Some lovebirds show no signs of disease.

One study was conducted on 32 peach-faced (rose-faced) lovebirds (*Apapornis roseicollis*) with skin and feather problems. Birds with chronic ulcerative dermatitis (CUD), the feather-less syndrome (FLS) or polyfolliculitis (PF) were screened for avian polyomavirus (APV) and psittacine beak and feather disease (PBFD). Of the birds with CUD, greater than fifty percent were positive for APV, and approximately 20% were positive for PBFDV. Of the birds with FLS, 16% were positive for APV and 65% were PBFD positive. All birds with PF were negative for APV and PBFD. The history of all of these birds also indicated malnutrition (Harrison/Gerlach, personal communication).

A generalized feather disease is seen in African grey parrots infected with circovirus, but often the disease is confined to the tail feathers, or there may be no feather involvement at all. African grey parrots may show ectopic red feathers; however, this abnormal coloration may also be caused by nutritional factors.

Eclectus parrots do not show typical feather lesions of PBFDV, but affected birds may have a delayed molt and old, poor quality feathering. An older age of onset of clinical signs of circovirus has been noted in *Eclectus* spp.

Infection in cockatoos leads to deformed feathers, feather loss and variable skin lesions. Beak lesions are less common than feather changes but are a prominent feature of this disease in some species of *Cacatua*. Variable necrosis and loss of keratin can be seen. Secondary candidiasis of the beak is common in affected cockatoos (Fig 13.8).

Necrosis and annular constriction of the base of the feather shaft and hemorrhage in the feather pulp are noted. There may be severe shedding of affected feathers. Affected feathers are stunted and may have thickened, hyperkeratotic sheaths, pulp hemorrhage, annular

Fig 13.8 | Severe feather loss and dystrophy as well as beak necrosis in a cockatoo with circovirus infection.

Fig 13.9 | Detail of feathers from Fig 13.8.

Fig 13.12 | Columbiforme circovirus.

Fig 13.13 | Columbiforme circovirus.

constrictions of the calamus, curling or stress lines on the vanes (Fig 13.9). Discoloration of feathers may be the initial sign in some birds. As mentioned above, African grey parrots may develop red feathers, and yellow feathers have been seen to replace green feathers in other species of parrots.

Gross lesions of circovirus infection are usually not seen in non-psittacine birds; however, feather dystrophy similar to that seen in psittacines has been reported in pigeons, doves and finches (Figs 13.10-13.13).

Polyoma/Papilloma Virus

Papilloma virus can cause proliferative skin lesions that are multiple and may superficially resemble mite infestation (Fig 13.14). This has been confirmed in African grey parrots. The lesions are fronds of hyperplastic epithelial cells supported by a vascular stroma. Radiosurgery, electrocautery and cryosurgery have all been utilized to resect the papillomas and to attempt to stimulate an immune response.

Fig 13.14 | Viral-induced papillomas on the face of an African grey parrot.

Polyomavirus was originally reported as a disease of budgerigars with feather loss. Primary feathers may appear abnormal. Polyomavirus infection is also seen in other psittacine species and grossly there may be dermal/follicular hemorrhage. See Chapter 32, Implications of Viruses in Clinical Disorders.

Poxvirus

This is an ubiquitous viral infection seen in all avian species. Fortunately the pox virus is relatively speciesspecific. Lesions are common on the head face and feet, but can also be present in other locations (Fig 13.15). The lesions are proliferative and may have rough or smooth surfaces depending on chronicity, self-trauma and the degree of secondary bacterial infection. In some cases much of the superficial portion of the lesion can be comprised of necrotic debris and crusts associated with bacterial or yeast infection, and care must be taken to ensure that any material removed for biopsy or cytology contains epidermal tissue (Fig 13.16). If no epidermis is present the correct diagnosis will probably not be made. Impression smears will contain epithelial cells with ballooning degeneration and cytoplasmic inclusion bodies (Fig 13.17).

The severity and location of lesions will dictate whether euthanasia is indicated or if treatment should be

Fig 13.15 | Facial lesions due to poxvirus infection in a canary.

Fig 13.19 | Color change in feathers secondary to nutritional problems, possibly a carotene deficiency.

Fig 13.20 | Stress bars in growing feathers. This is a nonspecific change that can be associated with a variety of insults during feather formation.

attempted. Despite supportive care, permanent deformity of eyelid margins and other facial tissue is common.

Herpesvirus

In cases of systemic herpes infection there is occasionally involvement of the epidermis of the skin or feather leading to necrosis and inclusion body formation. Since the generalized disease is usually catastrophic, little attention is paid to what may be grossly minimal skin lesions. In some psittacines, particularly macaws and cockatoos, proliferative lesions of the lower legs and feet have been described due to a herpes virus infection. Solitary or multiple proliferative nodules or plaques are more common in Cacatua spp., while depigmentation is more often encountered in macaws (Fig 13.18). The presence of these lesions in susceptible species should lead to herpes virus infection being included in the differential diagnosis.

Non-Infectious Disease

NUTRITIONAL/METABOLIC

A number of specific and non-specific nutritional problems can result in poor feather quality and skin disease. This may be the most common cause of primary feather abnormalities. See Chapter 6, Maximizing Information from the Physical Examination.

Depigmentation or altered pigmentation, improper molting and poor quality feathers can be seen (Figs 13.19, 13.20) (see Chapter 4, Nutritional Considerations). Gross changes are rarely specific. These lesions are not inflammatory, but poor nutrition can predispose the bird to skin infections and subsequent inflammation.

Metabolic disease could also result from failure of

proper nutrient metabolism even though nutrition is adequate. Gastro-intestinal, hepatic and pancreatic diseases are potential underlying causes. The diagnostic approach to chronic non-inflammatory skin disease should include examination and laboratory testing to rule out disease processes in internal organs.

PHYSICAL/ENVIRONMENTAL **AGENTS**

Trauma, burns, excessive cold and other physical factors often cause skin lesions, and although the cause may be obvious, histories are occasionally not obtained (Tables 13.3-13.5). Gross changes include loss of feathers, varying degrees of hemorrhage, necrosis, and superficial crust formation. Severe necrosis and sloughing of epidermis and possibly portions of dermis can be seen in injuries due to both heat and cold. Discoloration of the lesions is variable. Traumatic injuries are characterized by variable amounts of hemorrhage, edema and inflammation, depending on severity of the insult and time elapsed prior to examination (Figs 13.21, 13.22).

Beak trauma is a common presentation in psittacines. Injury from a bite from another bird is the most frequent cause. Damage from cage wires or cage equipment is also common.

Treatment and prognosis depend entirely on the severity of the injury. If proper beak occlusion is maintained, then treatment can be limited to prevention of infection. Topical and systemic antibiotics are warranted if the injury sustained is extensive or deep.

A hemostatic matrix such as Surgicell®d can be used to both stop bleeding and to provide a slow release of antibiotic. Antibiotics that are used in polymethyl methacrylate applications should provide a selection that is not tissue toxic and has good bioavailability (see

Fig 13.21 | Subcutaneous hemorrhage secondary to trauma.

Fig 13.22 | Severe edema of the subcutis following trauma.

Table 13.3 | Thermal Burn Treatment Protocol

- Stabilization of patient first:
 - 1. Fluids, electrolytes
 - 2. Treat for potential septicemia/endotoxemia
- · Topical treatment if weight bearing surfaces affected (ie, plantar surfaces of feet)
- · Bandaging if potential exists for self-mutilation of affected

Table 13.4 | Treatment of Band Injuries

(Figs 13.23-13.25)

- Removal of band with minimal additional tissue damage (ie, Veterinary Specialty Products band cutters)^b
- · Assessment of distal foot for viability.
- · Hydroscopic dressing to preserve tissue, vascularity and innervation (ie, Biodres®)c
- · Antibiotics as indicated for prevention of infection; both topical and systemic
- · Prevention of self trauma and frequent reassessment for continued viability and absence of infection.

Table 13.5 | Broken Blood Feather Treatment

- Keep quiet and confined to allow blood pressure to lower and bleeding to stop.
- · Apply a styptic powder to the broken feather area or twist off and apply to the tip.
- If occurs in the hospital, observing the bird for a few hours after powdering is often indicated to prevent excitation and subsequent bleeding in transport.
- When danger of hemorrhage is no longer present, assess feather damage.
- May trim end of feather to decrease movement or pain.
- Pulling of affected feather may result in follicular damage and abnormal growth of subsequent feather.
- Imping may be indicated for cases of chronic/repeat
- · Long-term treatment for recurrent blood feather trauma,
 - 1. Wing trim should be redesigned (see Chapter 1, Clinical Practice).
 - 2. Nutrition should be assessed (see Chapter 4, Nutritional Considerations).

Chapter 9, Therapeutic Agents).

More extensive trauma that either involves the occlusal surfaces or the growth plates of the beak warrants a guarded prognosis (see Chapter 14, Evaluating and Treating the Gastrointestinal System). Attention must be paid to adequate supportive care including analgesia, and maintenance of fluid and caloric intake.

BUMBLEFOOT/PODODERMATITIS: DECUBITAL SORES

Plantar decubital ulceration is common in older, obese and nutritionally deficient psittacines. See photos and classification of fat deposition in Chapter 6, Maximizing Information from the Physical Examination. Amazons, budgerigars and cockatiels are over-represented in the current population. Vitamin A deficiency weakens the epithelium of affected birds (see Chapter 4, Nutritional Considerations). Obesity and inactivity produce excessive pressure on plantar surfaces. Subsequent erosions and then ulcers occur. Localized staphylococcal infection is a common sequela (Fig 13.26).

Presentation may be subclinical and encountered on a routine annual examination. Correction of the underlying predisposing factors will often reverse this disease process. Perches must be altered in diameter and texture. The application of Vetrap®e or a similar product to the perch provides both padding and change in diameter when the material is wrapped at varying intervals and thicknesses. Diet should be corrected to decrease caloric intake and increase general nutritional balance, with emphasis on replacement of Vitamin A precursors (see Chapter 4, Nutritional Considerations).

More advanced cases of decubital ulceration require additional therapy. Systemic infection may be involved, and a complete blood count should be performed. Bandaging of the feet with the application of topical

Fig 13.23 | Leg band injury. Aluminum breeder band is embedded in skin and underlying tissue.

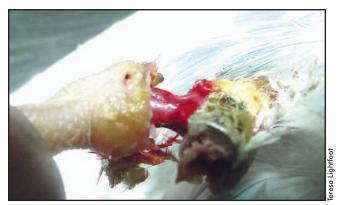

Fig 13.25 | Leg band injury. Although minimal viable tissue remains beneath the removed band, the innervation and circulation to the foot are still intact. Frequent bandage changes allowed this area to granulate and amputation was avoided. However, many band injuries of this severity will require amputation and the owners should be so forewarned.

Fig 13.24 | Leg band injury. Removal with the appropriate equipment is necessary to prevent fracturing the leg. In this case, band cutters by Veterinary Specialty Products, Boca Raton, FL, USA, were used.

Fig 13.26 | Bacterial pododermatitis. This lesion usually develops following pressure necrosis with a subsequent bacterial infection.

antibiotic and sufficient padding to reduce and better distribute pressure on the plantar surfaces is required in many cases. Pain relief in the form of NSAIDs (nons-

Table 13.6 | Treatment of Decubital Sores (Bumblefoot)

- Topical antimicrobials
- Hydrophilic dressings
- Padded foot bandages
- Anti-inflammatory/analgesics (ie, butorphanol/meloxicam)
- · Systemic antibiotics when indicated
- Consider use of antibiotic impregnated matrix
- · Debridement and suturing of more extensive lesions
- Long-term treatment requires owner compliance
 - 1. Alter/pad perches
 - 2. Exercise
- Assess and alter diet with particular attention to correcting obesity and providing adequate Vitamin A precursors (See Chapter 34, Surgical Resolution of Orthopedic Disorders and Chapter 4, Nutritional Considerations).

teroidal antiinflamatory drugs) or synthetic opioids may be needed (Table 13.6) (see Chapter 9, Therapeutic Agents). Debridement should be approached cautiously, since significant bleeding can occur from the decubitus.

When osteomyelitis is involved, the prognosis for recovery decreases dramatically. If systemic infection and pain can be controlled, therapy can be approached as above. The owner must be forewarned that the therapy will be of long duration and the prognosis is guarded. Ethical considerations arise when the degree of affectation is such that the bird can not stand without severe pain.

Endocrinopathies

Endocrine disorders can lead to generalized feather loss and abnormal feathering. There is usually no specific pattern or features that grossly indicate endocrine disor-

Fig 13.27 | Excessive fat deposits in the skin of a bird with hypothyroidism.

ders. To confirm a diagnosis of endocrine related skin disease, appropriate clinical laboratory testing is necessary. Confirmation can also result from finding appropriate endocrine gland lesions at necropsy (Fig 13.27). Although currently Thyroid Stimulating Hormone (TSH) for avian thyroid stimulation assays is not commercially available, research has shown that a 2 to 4 fold increase in circulating T_4 is a normal response in birds to administration of TSH. Interpretation of a baseline T_4 level has limitations as it does in domestic pet medicine, but may be useful diagnostically (see Chapter 19, Endocrine Considerations).

HYPERSENSITIVITY

Allergic skin disease in birds is occasionally reported, but is not well documented, and confirmation can be difficult. Gross changes include feather loss (often self-induced), reddening and occasionally, surface exudates. Some of the gross lesions may be secondary to self trauma.

Periocular and occasionally periaural pruritic, hyperkeratotic lesions are observed seasonally in outdoor birds in the southeastern US. When a biopsy is performed and these birds are housed indoors pending receipt of histopathology results, the lesion generally clears. Both pollen and insect sensitivity have been theorized.

Definitive diagnosis of allergic skin disease is difficult. Food elimination has lead to improvement in some cases (see Chapter 4, Nutritional Considerations: Section II, Nutritional Disorders) and successful treatment with anti-inflammatory drugs is presumptive evidence of allergy. The greatly diminished response of the avian patient to histamine administration has hindered the development of avian skin testing methods. Recent research has established positive and negative controls and preliminary standards for this testing. Diagnostic skin testing for

avian patients may be of great benefit in separating this category of disease from other conditions.

According to Patricia MacWhirter, DVM (personal communication, December 2003) an early researcher into avian intradermal testing: "Intradermal skin testing can be carried out in birds using the apteria on either side of the sternum. A statistically significant difference has been found in the occurrence of positive intradermal skin test reactions to Aspergillus, sunflower, house dust mites (D. pteronyssinus and D. farinae) and/or maize (corn) in a variety of psittacine species showing evidence of feather plucking, feather chewing or self injurious behavior compared with normal birds. This suggests that allergy may play a role in the occurrence of these syndromes. However, response to treatment by attempted avoidance of the suspected allergen(s) or the use of vaccines has to date often not been successful. Skin testing can be problematic to carry out because of the need for fresh allergens and accurate injection, the small area of bare skin available and difficulties in getting consistent results with positive controls. While promising, the technique is probably best suited to specialist dermatology practices and more research is needed before it can be routinely recommended." See Chapter 4, Nutritional Considerations.

Chronic Internal Disease

In many cases of chronic internal disease, including infectious, degenerative and neoplastic conditions, there is poor feather quality and loss of feathers.

NEOPLASIA

(See Chapter 20, Overview of Tumors).

Epithelial

Epithelial tumors originate in the surface epithelium, follicular epithelium or the uropygial glands. The uropygial gland may become abscessed as a result of occlusion of the papilla. This condition is treated much like an anal sac abscess in a dog, with debridement, reestablishment of patency of the duct and antibiotics as indicated. In some cases, neoplasia of the gland may underlie the infected state. Uropygial gland tumors can be either adenomas or carcinomas, and gross differentiation is difficult. Both will present as swellings that may be secondarily inflamed in some cases. Adenomas are usually well circumscribed and encapsulated with carcinomas being less differentiated and more infiltrative into surrounding tissue. See Chapter 35, Surgical Resolution of Soft Tissue Disorders for surgical considerations.

Fig 13.28 | Aggressive squamous cell carcinoma with loss of normal skin and severe secondary inflammation.

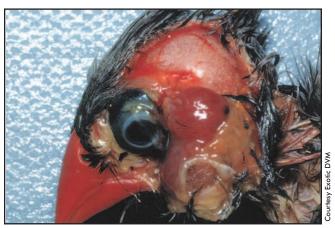

Fig 13.30 | Circumscribed red mass consistent with hemanaioma.

Papillomas of the skin are not common and may be virally induced in African grey parrots (see previous discussion).

Squamous cell carcinomas are often ulcerated and hemorrhagic as well as infiltrative (Fig 13.28). They may involve any portion of the skin and no particular site predilection has been identified. In some cases there is no obvious ulceration or inflammation in the early stages. Metastasis is not common, but occurs, particularly in chronic cases. This neoplasia often appears grossly as a delayed or non-healing cutaneous infection, and diagnosis is therefore often delayed.

Basal cell tumors often originate in feather cysts, and although expansile, are usually benign.

Mesenchymal tumors include those of vascular, fibrous, adipose and connective tissue origin. These tumors originate in the dermis or subcutis but may expand to involve the epidermis with secondary ulceration. Gross differentiation can be difficult with malignant tumors. Lipomas are common and have the gross appearance of a mass of normal fat (Fig 13.29). Hemangiomas are often dark red and hemorrhagic. They must be differentiated

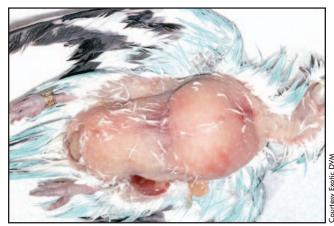

Fig 13.29 | Large mass typical of subcutaneous lipoma.

Fig 13.31 | Deeply located fibrosarcoma replacing soft tissue and bone.

from melanomas (Fig 13.30).

Fibromas and fibrosarcomas may both be seen but the later are more common. They present as nodular masses that may be ulcerative and infiltrative into deep tissues (Fig 13.31).

Dermal lymphosarcoma may present as a diffuse thickening of the skin with loss of feathers. This condition can be misdiagnosed as chronic resistant inflammation unless biopsied.

Melanocytic Tumors

Melanoma has been diagnosed in several psittacine birds. The tumor is not common and is usually malignant. These tumors often occur on the face and may involve the beak. They are brown-black, raised masses with poorly defined margins (Fig 13.32).

Mast cell tumors have only been reported in chickens and owls.

Granular cell tumors are infrequent in birds, and are seen primarily in psittacine birds, particularly Amazon

Fig 13.32 | *Eclectus* spp. female with malignant melanoma of the face and cere.

Fig 13.34 | Seven year old male Eclectus with xanthoma. This bird had been feather picking for 5 years. Hormonal manipulation and psychotropic drugs had temporarily decreased his plucking, but were not curative. When the xanthoma developed, dietary change to an organic formula resulted in resolution of the xanthoma and decreased feather destructive behavior.

Fig 13.33 | Xanthoma that has replaced much of the wing. This is a common location for the condition.

Fig 13.35 | Same Eclectus after 9 months of dietary correction, with no additional therapy.

parrots. They are small smooth nodules. (See Chapter 20, Overview of Tumors).

Non-neoplastic Proliferative Lesions

Xanthomatosis is a condition of uncertain etiology. Xanthomas are seen most commonly in cockatiels and budgerigars and usually are present on the wing as a variable-sized, yellow mass (Fig 13.33). Alternate common presentation sites include the sterno-pubic area and the keel. Surgical resection may be necessary in advanced cases and in those where the affected area is traumatized. In some species and some cases, nutritional therapy has been reported as successful. Feeding a balanced diet with increased Vitamin A precursors is the predominant dietary change initiated in the therapy of affected birds (Figs 13.34, 13.35).

Feather Destructive Behavior

Various degrees of feather destructive behavior, from over-preening to feather plucking and self-mutilation, are commonly encountered in avian practice. Based on skin biopsies, many of these cases have an underlying lesion that would account for pruritus and self-trauma. In some birds there is no evidence of skin or systemic disease or condition and these cases are considered behavioral problems after other causes have been ruled out. Since self-trauma can lead to lesions, histologic changes must be carefully assessed before a diagnosis of behavioral feather picking is made. In addition to complete physical and laboratory examination, history is very important for a proper diagnosis of this condition. (See Chapter 3, Concepts in Behavior and Chapter 4, Nutritional Considerations).

Skin Conditions

Several syndromes with no identified etiologies are commonly recognized by practitioners. These include chronic ulcerative dermatitis, Quaker (Monk) parakeet (Myiopsitta monachus) mutilation, and Amazon foot necrosis.

CHRONIC ULCERATIVE DERMATITIS

Chronic ulcerative dermatitis (CUD) is commonly reported in lovebirds and presents as self-trauma. The affected area is usually the patagium or neck and back. A linear lesion is generally encountered, and the bird often presents with either a chronic scarified area or with an acutely lacerated and hemorrhagic wound. As discussed under viruses, recent research on a small population indicates that polyoma virus, circovirus or both may be involved in this syndrome. The finding of a viral etiology in some cases of chronic ulcerative dermatitis in lovebirds would be consistent with reports of flock outbreaks of this condition. Other cases seem to occur in isolated individuals. Antibiotics are often clinically useful in controlling what is likely a secondary bacterial infection. Elizabethan collaring may be necessary to prevent self-mutilation and blood loss. Even when the primary lesion is healed, scar tissue often restricts movement and recurrence of self-mutilation is the rule. Some practitioners have associated Omega-3 fatty acid supplementation with clinical improvement. Use of psychotropic drugs and/or antihistamines has been reported with equivocal results.

QUAKER MUTILATION SYNDROME

A syndrome in Quaker (Monk) parakeets has been noted for many years in which sudden and aggressive self-mutilation is encountered (Table 13.7). Feather destructive behavior does not seem to be a precursor to this syndrome. The mutilation is often directed at the neck and chest area. Self trauma can include fatal damage to the crop and the jugular vein. With no etiology yet determined, treatment is limited to providing a mechanical barrier to the self-trauma and supportive care. Due to the severity and chronicity of this syndrome, euthanasia is often elected. Increased submissions for pathology may identify an etiology. Theories of potential etiologies and/or associated conditions include: viral, obesity, hepatic lipidosis, pancreatic insufficiency and lipemia (M. Rae, personal communication, 2002).

AMAZON FOOT NECROSIS

Amazon foot necrosis has historically been more prevalent on the west coast of the USA than in other areas.

Fig 13.36 | Bandaging for Amazon foot necrosis. Topical antimicrobial agents and hydrophilic bandage material may aid in healing. Bandaging both feet, even if only one is affected, tends to divert the patient's attention and prevent removal of the bandaging.

Table 13.7 | Treatment Protocol for Quaker **Mutilation Syndrome**

- E. collar often necessary to prevent severe/fatal self-mutilation.
- Be aware that self-mutilation may be displaced to an accessible body part.
- · Diazepam or other anti-anxiety/anti-psychotic drug
- Antibiotic for secondary infection.
- · Wound dressing as needed.
- · Owners should be informed of guarded prognosis.

The potential for a contact dermatitis would suggest that prior to handling these birds the owners wash their hands to rid them of residual nicotine, hand lotions, etc. Inhalant hypersensitivity has been theorized. Nutritional deficiencies or toxicities and hormonal influences have also been suggested. A recurrence and seasonality is commonly reported (Fig 13.36).

POLYFOLLICULITIS

Follicular malformations and dystrophy are occasionally seen. The most recognized has been called "polyfolliculitis." This is a misnomer as in many cases there is no inflammation. The condition is seen in budgerigars, cockatiels and lovebirds and presents as multiple feather shafts from a single follicle. Feathers are thick and short and may have retained sheaths. Grossly they present as fluctuant subcutaneous swellings that contain slightly viscid fluid.

Calcinosis circumscripta is an unusual condition in birds. It presents as nodular lesions that may have a white, chalky appearance grossly.

OTHER SKIN CONDITIONS

Occasionally severe inflammation is seen associated with collagen necrosis. A severe granulocytic response is present, and many of these cells may be eosinophils, however they are difficult to distinguish from heterophils

histologically. The lesion is similar to idiopathic collagenolytic inflammation seen in several mammalian species.

Autoimmune skin disease has not been documented in birds, but several cases with intraepidermal pustule formation and acantholysis have been seen. Unfortunately these few cases were lost to follow-up.

In many skin diagnoses there are inflammatory lesions whose exact etiology cannot be determined. Based on

the pattern and type of inflammation a tentative diagnosis may be made, but until many more cases with complete histories and follow-up information become available, many lesions will have obscure origins.

Evaluating and Treating the

Gastrointestinal System

STACEY GELIS, BSc, BVSc (Hons), MACVSc (Avian Health)

The avian gastrointestinal tract (GIT) has undergone a multitude of changes during evolution to become a unique anatomical and physiological structure when compared to other animal orders. On the one hand it has evolved to take advantage of the physical and chemical characteristics of a wide variety of food types.1 On the other hand, it has had to do so within the limitations of the requirements for flight.2 To this end, birds have evolved a lightweight beak and muscular ventriculus, which replaces the heavy bone, muscular and dental structure characteristic of reptiles and mammals. The ventriculus and small intestine are the heaviest structures within the gastrointestinal tract and are located near the bird's centre of gravity within the abdomen. The overall length of the GIT is also less than that of a comparable mammal, another weight-saving flight adaptation. Interestingly, these characteristics are still shared with the flightless species such as ratites and penguins. In addition, the actual digestive process needs to be rapid to support the high metabolic rate typical of flighted birds.3

Gastrointestinal adaptations to the wide range of ecological niches that birds occupy mean that birds can take advantage of a huge variety of foodstuffs. The GIT hence shows the greatest degree of diversity of all the organ systems between different avian taxa. However, the pressures of convergent evolution have also meant that many distantly related species have developed a similar gastrointestinal anatomy to take advantage of particular food niches.^{3,4} Examples of these will be presented in the discussion of each section of the GIT.

The avian GIT also has the capacity to accommodate changes which occur during the life cycle of a bird and also which occur due to seasonal environmental conditions and hence differing available foodstuffs over the course of a year or years.

Anatomy and Physiology of the Digestive Tract

The avian gastrointestinal tract is a double-ended open tube (as is also seen in mammals) that begins at the beak and finishes at the vent. In sequential order it is composed of a mouth, esophagus, crop, proventriculus, ventriculus (gizzard), intestine, ceca, rectum and cloaca. Some of these structures may be vestigial or even lost during the evolution of some species. The progress of food through the tract follows a specific digestive sequence including premoistening and softening, acidifying, grinding, hydrolyzing, emulsifying and propulsion of the end products. This propulsion is not always in a unidirectional pattern as will be outlined later.

BEAK, MOUTH, TONGUE AND PHARYNX

The beak or bill is the avian substitute for teeth and lips and forms the entrance to the oral cavity. It is used for grasping and processing foods, as well as for climbing and various behavioral functions such as biting, preening and displaying. It consists of the mandibular bones, the premaxilla and maxilla and their horny covering, the rhamphotheca. The upper bill covering is known as the rhinotheca, which covers the premaxillary bones and partly covers the maxillary bones. It is usually composed of hard keratin, although in waterfowl only the tip is hard, and in shorebirds the entire bill is relatively soft.2 The keratin layer covering the lower bill or mandible is known as the gnathotheca. Both keratin layers are continually lost by wear and replaced by new growth. Beak shape is influenced by the location and rate of wear and hence regrowth, which is in large part determined by diet. This may subtly change over time as food types change. For example, the anterior of the outer edges of the beak, the tomia, may be sharp in some species to assist in cutting seed coats.1 Other anatomical characteristics further facilitate the feeding process. The lower beak is loosely attached to the skull, allowing for a large gape. The size of the gape determines the maximum size of food particles that can be swallowed. This is particularly important in fruit-eating species such as toucans. Psittacines typically have a very powerful beak. The rhinotheca is broad with a curved rostral tip, giving the typical hooked appearance. The gnathotheca has a blunt

chisel-shaped rostrum that pushes against a prominent ridge found on the undersurface of the rhinotheca. Psittacines also have developed a prokinetic maxilla that allows them to move their mandible and maxilla independently. This allows an increased gape of the beak, an improved ability to position food items in the beak, as well as providing flexion and shock absorption associated with seed and nut cracking and also with some behaviors such as pecking.5 The strength generated by these structures is exemplified by the Hyacinth macaw's ability to crack palm nuts in order to extract the kernel. Pigeons, on the other hand, have a typical seedeater's bill being mildly conical.6 It is also not as keratinized as in psittacines. Raptors tend to also have curved, hooklike bills but lack the prokinetic maxilla.6 Their bill is adapted to tearing and shredding meat. "Darwin's Finches" on the Galapagos Islands best exemplify the variability in beak shape brought about by the need to adapt to changing environments. Here, the species are all similarly colored, but are separated on the basis of bill shape and feeding habits. Each has evolved to its own ecological niche, avoiding interspecific competition.7 The avian bill is often endowed with sensitive nerve endings, particularly in species that use the bill to probe for food. Examples include waders, diving ducks and woodpeckers.3

Unlike mammals, birds do not have a soft palate or a pharyngeal isthmus, nor do they have a sharp demarcation between the mouth and pharynx.2 Instead, they have a combined oropharynx (Figs 14.1a,b). A longitudinal fissure, the choana, which connects the oral and nasal cavities, splits the palate. The choana is variably developed. In pigeons it is narrow and lacks papillae. In falcons it forms a narrow "V"- shape with few papillae. In psittacines, it forms a wide "V" and is bordered by caudally-pointed sensory papillae.6 The choanal slit closes during swallowing. The infundibular cleft is located at the caudal edge of the choana and is the caudal opening of the left and right pharyngotympanic (Eustachian) tubes (Rami infundibuli Fig 14.1a) from the middle ear.6 The palate forms a roof over the anterior part of the oral cavity. In finches, canaries, budgerigars and cockatiels it contains two ridges that assist in the removal of husks from seeds before ingestion.1

The tongue (Fig 14.1b) originates from the floor of the oropharynx and is mobilized by the hyoid apparatus and its multiple articulating bones and musculature. It functions to collect, manipulate and swallow food. Again, great species diversity exists in tongue development. The tongues of passerines and pigeons tend to be smooth, short and simple. Psittacines are unique amongst birds in having additional striated muscles in the anterior regions of their tongues that are independ-

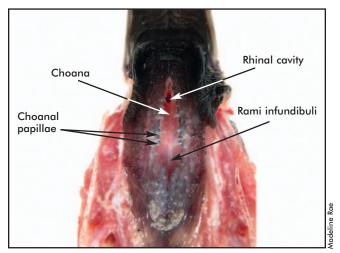

Fig 14.1a | Ventral dorsal view of the palate area of the orapharnyx.

Fig 14.1b | Frontal view of orapharnyx of an Amazon parrot. T=tongue, M=mandible, C=choanal slit. Note the reduction of papillae.

ent of the hyoid apparatus and permit added flexibility and manipulative capabilities. The typical psittacine tongue is thick and muscular and its maneuverability allows for the extraction of seeds and nuts from their husks, cones or pods. Lories and lorikeets have relatively long tongues that end in fine papillae that aid in the harvesting of pollens and the collection of nectar from flowers by capillary action.89 In birds of prey the tongue is rasp-like, with a roughened tip and many small caudally pointed papillae near the base. 6,10 In ducks and other waterfowl which strain food particles, the rostral part of the tongue is scoop-like and has a double row of overlapping bristles on its lateral borders. These bristles work with the beak lamellae to filter particles.2 It is interesting to note that birds have poor taste sensitivity compared to humans. For example, parrots have approximately 350 taste receptors compared with 9000 in humans¹¹, and chickens have up to 300 taste buds.¹² These are mostly located on the palate near salivary glands and on the posterior tongue. However, the beak, tongue and oral cavity have many touch receptors that make the mouth an important sensory area.1

The laryngeal mound lies immediately behind the tongue in most species and contains the glottis, the opening to the trachea. In most species the glottis lies directly under the caudal portion of the choana or just caudal to the choana in raptors. The laryngeal mound contains rows of caudally directed papillae that assist in the propulsion of food towards the esophagus during swallowing.² Birds lack an epiglottis.

Salivary Glands

There is great species variability in the number and distribution of salivary glands.² Granivorous species such as some parrots, pigeons, chickens and finches have a large number of glands to assist in swallowing the dry feeds

they ingest. These glands are located in the roof, cheeks and floor of the oropharynx. Raptors have less developed salivary glands and piscivorous (fish-eating) species have poorly developed glands, or lack them all together. This is presumed to be related to the lubricated nature of the food they ingest. The content of the saliva produced also varies between species. The salivary glands of house sparrows secrete significant amounts of amylase whereas those of chickens and turkeys secrete little amylase.¹³

Esophagus and Crop

The esophagus is a thin-walled distensible tube that delivers food from the oropharynx to the proventriculus. It allows birds to swallow their food items whole. In birds the esophagus is divided into a cervical and a thoracic region. In the budgerigar, it lies dorsal to the trachea in the anterior regions of the neck and then runs along the right side.14 The esophagus' distensibility is facilitated by a number of longitudinal folds. These folds are large and extensive in owls (Strigiformes) and species that swallow whole prey items, or those that store large amounts of food material such as gulls (Larus spp.). By contrast, parrots exhibit minimal esophageal fold development and possess a relatively narrow esophagus.6 Mucus-secreting glands are present in the esophageal mucosa of most birds, particularly in the thoracic esophagus. These glands are actually absent from the cervical esophagus of budgerigars.

The avian esophageal wall consists of a mucosa, submucosa, a muscular tunic and a serosal layer. It generally contains only smooth muscle cells with a circular muscle layer predominating. 10 Peristaltic contractions of inner circular and outer longitudinal muscles propel food posteriorly through the esophagus. 1

The crop or ingluvies is an expansion of the cervical

esophagus that functions as a food storage organ.^{1,2,6} It mostly lies on the right side of the neck and when distended may also lie on the left side and will rest on the furcula. The crop has varying degrees of development in different species. In its simplest form, it is merely a spindle-shaped enlargement of the cervical esophagus. This arrangement is seen in ducks (Anas spp.) and owls.6 Parrots have well-developed crops that lie at the caudal cervical esophagus. A prominent right pouch and a small left pouch typifies parrots. Pigeon crops have a more complicated structure. Both right and left lateral pouches or diverticulae are well-developed. The lateral pouches produce a holocrine secretion from the crop epithelium — "crop milk" — which is fed to the squabs during the breeding season.15 It is produced in response to prolactin. It contains 12.4% protein, 8.6% lipids, 1.37% ash and 74% water.² Therefore it is mainly a protein and fatty acid source for these chicks, and is devoid of carbohydrate and calcium. Both males and females produce crop milk. Sheets of striated muscle that attach to the crop adventitia support the large crop. Parrot and pigeon crops possess a functional sphincter at the junction of the crop and the thoracic esophagus. This helps to form and regulate the boluses of food being propelled to the proventriculus.6 It should be noted that birds lack the true upper and lower esophageal sphincters found in mammals.1 Some granivorous species such as the European goldfinch (Carduelis carduelis) lack a true crop but have a very expandable esophageal pouch that can store food items. Gulls, penguins and ostriches lack a crop but have a very distensible esophagus.2

The crop's storage function allows birds to ingest and store feed in the evening before roosting, thus providing for overnight energy needs. It also allows birds to rapidly ingest food items in a short period of time, and then take refuge in safe cover where the meal can be digested at a more leisurely rate. The crop also acts to soften ingested food by holding swallowed water and by contributing mucus to the saliva. Enzymes within the food or microbes present in the crop may further contribute to digestion. 16,17 Any glucose released in the crop can be absorbed by the crop mucosa, but this is of minimal importance.2

The crop is particularly well-developed in chicks to store food fed by the parents. The parents of altricial chicks premoisten and soften food in their crops and esophagus before regurgitating it to their chicks. The crop also provides an important immunological function in pigeons feeding squabs.15

THE AVIAN STOMACH: PROVEN-TRICULUS AND VENTRICULUS

The avian stomach consists of 2 distinct structures, the

first part being the proventriculus or glandular stomach and the second structure is called the ventriculus (gizzard) or muscular stomach.

The relative size and shape of these structures is based on diet and is hence quite variable. In carnivorous and piscivorous species both structures are very distensible and may be difficult to differentiate grossly. This is due to the soft nature of their diet. In birds that eat hard food items, the proventriculus is relatively thin-walled and glandular. The ventriculus is muscular, thick-walled and powerful. The intermediate zone connects the two.^{2,6} This gastric arrangement is typical of granivores, omnivores, insectivores and herbivores and hence most of the commonly found species in captivity.

The proventriculus is confluent with the esophagus cranially but has its own distinctly different structure. It lacks ridges, except in carnivorous and piscivorous species, and is lined with a mucous membrane. Its epithelium contains two principal types of glands that make up most of the thickness of the proventricular wall.2 The first of these, the tubular glands, secrete mucus. The second type, the gastric glands, secrete hydrochloric acid and pepsin. This provides an acidic environment for digestion. Typically, the fasted chicken has a pH of 2.6, whilst that of a pigeon is 2.1.6 Nectarivorous parrots have gland-free spaces between the longitudinal rows of glands. This allows for distension of the glandular stomach that may be an adaptation to pollen digestion.16,18

The proventriculus contains two muscular layers, the innermost circular layer and the outer longitudinal layer. The outer longitudinal layer is poorly developed or absent in parrots, waterfowl and some passerines. In these birds the myenteric plexus is located immediately under the serosal layer rather than between the two muscle layers.2

The intermediate zone between the proventriculus and ventriculus is aglandular and lacks folds. In parrots and pigeons, it closes tightly during ventricular contractions to segregate the ventriculus from the proventriculus.6

The ventriculus or gizzard has evolved to mechanically break food down. Hence it is best developed in species that ingest hard foods such as granivores, 1,2,6 and also in insectivores that need to break down the hard exoskeletons of their prey.¹⁸ It is also the location where hydrochloric acid and pepsin can further chemically break food particles down. It consists of two pairs of opposing muscles. The caudoventral and craniodorsal thin muscles line the caudal and cranial sac of the gizzard respectively. The cranioventral and caudodorsal thick muscles are responsible for the powerful grinding

contractions seen in the gizzard.¹⁶ The asymmetrical arrangement of these four muscles provides mixing and grinding actions during contractions.1 The ventriculus is lined by the koilin, a cuticle layer, which acts as a grinding surface and protects the underlying mucosa from the acid and pepsin produced by the proventriculus. The koilin is made up of a combination of proteinaceous rod-like projections produced by the deep tubular glands lining the gizzard, together with desquamated epithelial cells that form a matrix. 1,2,6 The hardened composite frequently has raised areas and distinct longitudinal and transverse grooves that aid in mechanical breakdown of foods. It is thickest in species with well-developed, muscular stomachs. It is continuously worn and replaced in many species, but in falcons it may occasionally be sloughed and shed. The koilin lining may be green, brown or yellow in color due to bile staining caused by ventricular reflux from the small intestine. This is a normal finding.6

The gizzard is separated from the small intestine by a small pyloric fold that regulates the passage of food into the small intestine by slowing the movement of large particles. ¹⁹ In lorikeets and honeyeaters (both nectarivorous species), the proventricular and pyloric openings of the gizzard lie in a median plane, which is thought to allow rapid passage of ingesta. ⁸

It is interesting to note that the size of the gizzard can change with diet within the same species, being thicker and larger when dry seeds are eaten and softer and lighter in summer when fruits are eaten.¹

The role of grit in avian digestion is an interesting one. Insoluble grit may lodge in the gizzard and add to the maceration of the food, particularly in species that do not dehusk the seed before swallowing it, eg, pigeons, and galliforms like quail. It is controversial whether birds deliberately seek insoluble grit to aid in digestion or whether its ingestion is incidental to eating digestible foods or soils containing minerals and trace elements.⁶ Grit is absent from the stomachs of nectarivorous birds, which also have poorly developed gizzards.¹⁸

GASTRIC MOTILITY

Food passes through the proventriculus very quickly where it is coated with hydrochloric acid and pepsin, with little enzymatic digestion. Digestion is controlled by the vagus nerve and by the hormones gastrin, secretin, cholecystokinin and pancreatic polypeptides. The food is propelled into the ventriculus where most of the mechanical digestion occurs by a combination of coordinated muscle contractions and the action of grit. The exact process varies with species. In turkeys and parrots, for example, the muscles contract in a clockwise direc-

tion around the ventriculus. 6,20 The paired thin muscles contract first and the isthmus closes, segregating the ventriculus from the proventriculus. As these muscles reach maximum contraction, the pylorus opens allowing digesta to pass into the duodenum. The thin muscles then relax as the thick muscles contract. This coincides with the closing of the pylorus and the beginning of peristaltic contractions along the duodenum. The isthmus may also open to allow the passage of ingesta back into the proventriculus for the addition of fresh acid and pepsin, allowing additional time for the breakup of large lipid globules and the breakdown of proteins. In particular, lipid is retained in the anterior region of the tract and digested more slowly than are protein or carbohydrates.21,22 This cycle of contraction occurs as a seamless movement that gives the appearance that the gizzard is flipping.6 This coordinated complex of contractions is controlled intrinsically by the myenteric plexus.

Raptors have a more simple stomach arrangement that has to produce the pellets, indigestible contents of fur, bone, teeth, feathers, claws, as well as perform the normal digestive function. Neck extension and head pumping assist the peristaltic propulsion of food into the proventriculus. The stomach fills with digestive juices over the next hour and vigorous, high frequency waves of contractions occur in a clockwise direction from the isthmus to the pylorus. This is followed by a 7- to 9-hour period of chemical digestion where forceful proventricular contractions occur at low frequency. By the end of this period, digestion is complete. Next, a short phase of paired contractions removes any further liquid from the indigestible pellet. This is followed by a further 5- to 6hour phase of pellet compaction after which it is expelled by retroperistalsis. The timing of pellet ejection varies with the species.

INTESTINES AND PANCREAS

The small intestine is the main site for enzymatic digestion and nutrient absorption in the avian gut. It is less differentiated between species than are the more proximal regions of the gastrointestinal tract. The duodenum arises from the pylorus and forms a loop that encircles the bulk of the pancreas. The pancreas is trilobed in most species with the third lobe or splenic pancreas sometimes not being directly attached to the other two lobes. In budgerigars, the three pancreatic lobes are each drained by a separate duct. Two of these ducts empty into the distal duodenal loop adjacent to the bile duct whilst the other duct empties into the opposite side of the duodenum. 14 In pigeons, all three pancreatic ducts empty into the distal duodenum.6 The exocrine pancreas contains enzymes similar to those found in mammals such as amylase, lipases, trypsin and chymotrypsin,

carboxypeptidases A, B and C, deoxyribonucleases, ribonucleases and elastases.1 It also produces bicarbonate that buffers the intestinal pH. It is also important to remember that the intestinal wall mucosa also produces amylase, maltase, sucrase, enterokinase, lipases and peptidases and so contributes to enzymatic digestion.⁶ These enzymes are produced in response to duodenal distension, hydrochloric acid, vagal stimulation, cholecystokinin, secretin and vasoactive intestinal peptide.^{2,23} Birds have not been shown to possess any intestinal lactases so they should not be fed significant quantities of lactose-containing foods.²⁴ Amylase levels are actually highest in the jejunum, but the jejunum and ileum cannot be readily differentiated from the duodenum in birds. In general, the jejunum is thought to begin just after the ascending duodenal loop begins to turn back on itself, where the jejunal branches of the cranial mesenteric artery begin. The ileum is thought to begin at the vitelline (Meckel's) diverticulum and end at the recto-cecal junction.6 There is great variation in jejunal and ileal anatomy in different species.

Nectarivorous and insectivorous birds have shorter intestines than do similar sized granivorous or herbivorous species.25 This is believed to be due to the highly digestible nature of their diet.

The intestinal epithelium contains villi, microvilli and crypts. The villi's increased surface area allows efficient absorption of nutrients and their rich capillary system enables transport of these nutrients to the portal blood system. A thick layer of mucus produced by goblet cells in the epithelium protects the intestinal epithelium from the digestive juices and from physical abrasion, particularly anteriorly near the gizzard. Two muscle layers surround the intestine, the inner circular and outer longitudinal layers that allow mixing and propulsion of the digesta through the intestinal tract.

The avian duodenum is unique in its ability to exhibit both normograde and retroperistalsis. These retrograde peristaltic waves bring the digesta back towards and into the ventriculus, as is evidenced by the presence of bile staining in the ventricular koilin. These waves are powerful and visibly distinct from the normal peristaltic waves. They occur every 15 to 20 minutes in the turkey²⁰ and up to once a minute in parrots on a moderate fat diet.6

The liver also empties into the distal duodenum via the bile ducts. Its primary digestive function is the production of bile acids and salts that assist in the emulsification of fats, allowing their digestion by lipases. These acids and salts, together with cholesterol and phospholipids, are secreted into the bile canaliculi that drain into the bile duct. Gall bladders are present in raptors and waterfowl, but are absent in many psittacines and pigeons. 6,26

The ceca are important in fermentation of vegetable matter and in water balance and are hence most developed in chickens, ratites and ducks.²⁷ They are absent or vestigial in parrots and small insectivorous passerines, appearing histologically as a nodule of lymphatic tissue at the small intestinal-rectal junction. In the domestic pigeon they are entirely lymphatic in structure and are called the cecal tonsils. They are, however, well developed in herbivorous or omnivorous passerines.16

The avian rectum or colon is found between the ileocecal junction and the cloacal coprodeum. Except in the ostrich, it is very short and has a smaller relative diameter than the mammalian large intestine and is structurally dissimilar, being similar to the small intestine except for having shorter villi that are richer in lymphoid follicles. The avian rectum exhibits marked retroperistalsis, carrying urine from the urodeum and coprodeum into the colon up to the ceca.⁶ This allows for further water resorption in the colon and hence aids in water conservation. In the pigeon the rectum enters the coprodeum from the right side, whereas in the parrot it enters from the left side at a 60 to 90° angle.6

CLOACA

The avian cloaca is a three-chambered structure that is responsible for the terminal deposition of digestive, urinary and reproductive products. It is much wider than the rectum. The first, most proximal chamber, is the coprodeum into which the rectum empties. It is the largest chamber of the psittacine cloaca and has a flat, vascular, avillous mucosa, covered by columnar epithelium and an extensive branching vascular pattern. 6,28 It is separated from the second chamber, the urodeum by an encircling sphincter-like ridge, the coprodeal fold. This fold can completely close off the coprodeum from the other chambers of the cloaca, preventing contamination of eggs or semen during egg laying or ejaculation.

The urodeum is the smallest cloacal chamber in psittacines, columbiforms and falconiforms. It receives the ureters and also the oviduct in females and the ductus deferens in males. The ureters enter the urodeum on either side of the dorsal midline, and in pigeons and parrots these openings are simple. In females, the oviduct has a rosette-like opening on the left dorso-lateral wall. It is smaller and less prominent in juveniles and hence difficult to visualize in these birds.²⁸ A membranous tissue may occlude this opening in females that have not yet laid in species such as the ostrich.²⁹ In males, the ductus deferens enters the urodeum on symmetrical, raised papillae located on the left and right dorsolateral walls. It is separated distally from the proctodeum by the uroproctodeal fold. The urodeal mucosa is smoother and less vascular than that of the coprodeum.

The urodeum exhibits retroperistalsis, pushing urates and urine cranially into the coprodeum and rectum where water and solutes are further resorbed, thus maximizing water conservation. This retroperistalsis explains why urates and feces are sometimes intertwined when passed from the cloaca.

The proctodeum is the final cloacal chamber and is slightly larger than the urodeum in most species. The uroproctodeal fold is more developed dorsally and gradually loses prominence ventrally. This chamber is the most frequent site of papillomas in psittacines. It also gives rise to the Bursa of Fabricius on the dorsal midline just caudal to the uroproctodeal fold. The bursa is most prominent in the juvenile bird where its lymphoid tissue is responsible for the production of B-lymphocytes. In mature birds the lymphoid tissue involutes but the bursa's opening and chamber frequently persist and can be viewed during cloacoscopy. The timing of bursal involution is usually between 2 and 6 months of age, but varies between species.

The cloacal blood supply is via the pudendal artery and vein. Innervation is via the pudendal nerve that follows the ureters to the dorsal cloacal wall where the cloacal ganglia are found.²⁸ These are important surgical landmarks.

The final structure of the gastrointestinal tract is the vent, a transverse opening in the ventrocaudal body wall through which body wastes and reproductive products are expelled. It is demarcated by lips dorsally and ventrally and is surrounded by voluntary muscles that form a sphincter. This provides birds with some control over defecation. For example hens that are incubating may pass a large urofeces in the morning when nest changeover occurs. Some psittacines can also be toilet trained to defecate on command. The act of defecation involves the partial eversion of the vent lips, resulting in the formation of a circular orifice through which feces, urates and urine can be expelled.¹

Cloacal "sucking" has been noted in psittacines in juveniles and breeding females, where material is brought in from the outside via the vent lips under negative pressure. ^{28,31} In chicks, this is thought to have an immune stimulation function by exposing the B cells in the bursa to external antigens. In breeding females it is thought to facilitate sperm transport and hence fertilization in species where the male lacks a phallus. ³¹ See Chapter 18, Evaluating and Treating the Reproductive System for further discussion of the vent

Gastrointestinal Diseases

DISORDERS OF THE BEAK

Deformities

Deformities of the bill of young birds, both congenital and acquired, have been described. Congenital deformities have been mostly described in poultry and waterfowl. Some of these are part of a more generalized problem, such as Micromelic Syndrome of white Pekin ducklings, an autosomal recessive mutation which causes a short maxilla, reduced overall size, shortened limbs, cervical subcutaneous edema and abnormal feathering.32 Others are specific to the beak such as variations in the shape and curvature causing malocclusion, often leading to the maxilla being caught inside the lower mandible (prognathism) (Fig 14.2).33 "Scissor-beak" is a condition where the upper beak rhinotheca is bent to one side, resulting in the overgrowth of the gnathotheca in psittacine chicks (Fig 14.4a). The condition becomes progressively worse due to the continued forces applied during the bird's normal beak usage and as the chick grows.^{34,35} It has also been noted in other avian species such as ostriches,36 softbills and passerines32 where either the mandible or maxilla may deviate. Multiple potential etiologies have been described including heredity, incubation problems, malnutrition, infectious sinusitis, viral diseases and trauma.36,37,38*

In young psittacines, incorrect hand feeding techniques may result in bruising of the rictus on one side of the beak, leading to uneven growth and scissor beak.^{38,39} *Eds. Note: In most psittacine rearing facilities establishing a formulated diet program for adults and youngsters has eliminated these problems completely. Facial bones are not as malleable in properly fed parents or their offspring. Treatment involves altering the forces that direct the rostral growth of the affected part of the beak. Surgical techniques to achieve this have been described.^{38,40} In addition, revision of incubation and chick feeding practices and nutrition may be warranted.

Mandibular compression has also been described in young macaws.³⁵ Prognathism, where the upper beak tucks into the lower beak, is another congenital beak deformity sometimes seen in chicks, particularly cockatoos.^{35,41} The etiology of this condition is unknown. If attended to early, it can be corrected with physiotherapy by applying traction rostrally to the maxillary beak several times daily. If the maxillia is calcified, physiotherapy and beak trimming may help.⁴² In more severe cases, dental acrylic prostheses (Fig 14.3) can be applied to the tip of the maxillary beak to force it to stretch out over the mandible⁴¹ or KE wires and rubber bands or cable ties can be used in a modified Doyle technique (Figs 14.4α-f, 14.5α-f).⁴⁰

Fig 14.2 | Baby umbrella cockatoo with mandibular prognathism.

Fig 14.3 | Acrylic applied to beak tip to allow new growth pressure to overcome the prognathic condition. A metal transverse pin made from a hypodermic needle is often implanted to help the acrylic maintain adhesion to the beak.

Crusty scab-like lesions at the commisures of the beak have been associated with biotin and pantothenic acid deficiencies in gallinaceous birds and ostriches. 36,43 Vitamin D and calcium deficiencies have resulted in soft beaks due to insufficient mineralization in many species. 33,44 Malnutrition and hypovitaminosis A were associated with significant beak deformities in handreared African grey parrot (Psittacus erithacus) chicks (see Chapter 5, Calcium Metabolism).44 These were seen as significant grooved ridges and indentations of the rhinotheca and gnathotheca. Birds with rhinothecal overgrowth characterized by intralaminal hemorrhages have often been diagnosed with previous or current liver disease and malnutrition.44 Assessing liver function, correcting the diet and trimming the beak as required are all useful management tools.

Traumatic Lesions

Traumatic lesions to beaks are amongst the most commonly seen problems. These frequently occur as a result of intra- or interspecific aggression, parent birds that mutilate chicks, accidents or predator attack. Iatrogenic causes have also been described from incorrect handling, use of mouth specula or incorrect beak trimming.39 It should be remembered that the avian beak lacks a subcutis, and hence the thin dermal fibrovascular stroma is directly apposed to the periosteum. Therefore pressure necrosis of parts of the rhamphotheca and gnathotheca can lead to permanent beak defects.46 Immediate treatment for trauma cases involves stopping hemorrhage, counteracting shock via fluid therapy, providing analgesia and preventing infection. Nutritional support then needs to be provided.39,47 The decision as to how to best manage the injuries needs to be made early, to decide if indeed the bird is salvageable or if the

owner is prepared to accept the care and cost involved with long-term management. Loss of the distal third of the bill has potential for regeneration, at least in psittacines,48 but not in other species such as ostriches (Strutbio camelus) in which beak growth stops in adulthood.³⁷ Trimming and reshaping using a mild grinding tool, such as an electric motor drill, can treat minor distal fractures. Rhamphothecal fractures can be stabilized with tissue glues such as cyanoacrylate (Figs 14.6a-i). 49,50 More serious fractures may require surgery with pins, wires, sutures, plating or acrylic remodeling techniques, depending on species, patient size, nature and location of the injury or fracture (Fig 14.7).37,47,51,52 It should be noted that fractures and avulsions of the upper rhamphotheca are the most challenging due to the kinetic nature of the maxilla (in psittacines), the forces exerted and the presence of small bones.⁴⁷ Damage to the germinative layer of the rhamphotheca or gnathotheca or of the underlying bone means that the affected area will not regenerate keratin (Fig 14.8).50,52 If the associated beak structure has been avulsed and if the damage is great enough, the entire mandible or maxilla may be lost and not regenerate. Acrylic prosthetics have been used as a temporary means of restoring beak function and appearance until new keratin growth occurs.⁵² In permanent injuries, these prosthetic beaks need to be remodeled, replaced or reapplied on a regular basis, as they invariably work loose. In cranes, this is every 3 to 6 months.53 Natural prosthetic devices have been successfully used in toucans utilizing the beaks from dead birds of the same or similar species. The surgeon should instruct the owner that these prostheses are also, like the acrylic or metal repairs, only temporary.⁴⁷

Palatine bone luxation has been described in blue-andgold macaws (Ara ararauna) following trauma in which

Fig 14.4a | Scissor beak in an umbrella cockatoo.

Fig 14.4b | Bands used for beak orthodonture. A electrician's black cable tie and an orthodonture rubber band are shown.

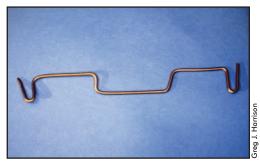

Fig 14.4c | The final shape of the transverse sinal pin for a beak traction technique.

Fig 14.4d | Band applied to beak with enough pressure on the transverse sinal pins to correct the deviation.

Fig 14.4e| Bandage material is placed over the rubber bands to avoid removal or becoming snagged.

Fig 14.4f | Several weeks after correction and removal of appliance. Traction was applied for 2 weeks.

the palatine bones became hooked onto the interorbital septum. 40,54 The luxation was reduced under general anesthesia by using digital pressure on the maxilla both directly and via an intramedullary pin placed through the infraorbital sinuses. 54

Infectious Causes of Beak Malformation

Various infectious disease processes can involve the beak. Psittacine circovirus disease (Psittacine Beak and Feather Disease) infects numerous psittacine species, both wild and captive, where it can cause beak lesions as part of the chronic presentation of the disease, particularly in young cockatoos. 55 Affected beaks typically become abnormally elongated and may develop transverse or longitudinal fractures. 56,57 In some cases only the tips may be fractured. There may be necrosis of the palate and ulcers of the mouth. As the disease progresses, the beak may fracture and avulse, exposing the underlying bone, which can be very painful. Secondary bacterial and fungal infections may complicate the infection and cause life-threatening disease. Diagnosis is by

PCR or HA (hemagglutination assay)^{55,56} for presence of the virus or HI (hemagglutination-inhibition) for antibody levels.⁵⁶ Histopathology of affected tissues is also useful. Severely affected birds are usually euthanized, as there is no specific treatment for this disease except for supportive care which includes maximizing hygiene, providing soft foods, treatment of any secondary infections and immunostimulation.

Poxvirus infections are seen on the unfeathered regions of many avian species, but less commonly in psittacines.⁵⁷ This *Avipoxvirus* classically causes raised lesions which may or may not become necrotic and then secondarily infected. These may be found on the beak or at the beak/skin margin and also in the oropharynx. The beak and mouth may become painful and disfigured, and the bird may show reluctance to eat. Transmission requires direct contact with open wounds or inoculation via an insect vector. In one case, the basal layers of the beak epidermis were infected causing sloughing of the keratinized layers.⁵⁷ Although species-specific strains are transmitted by mosquitoes, cross-species infections may occur,

Fig 14.5a | Young cockatiel that was having its beak ground as a first step in the therapy for prognathism.

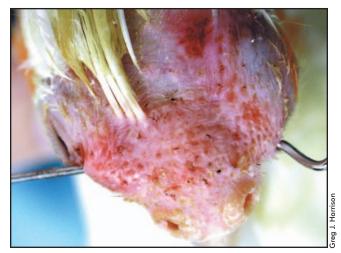

Fig 14.5c | The first hook is bent into one end.

Fig 14.5e | An orthodonture rubber band is placed around the left dorsal transverse sinus pin's hook and the ventral S-pin. A hemostat is placed around the tensed rubber band and stainless steel suture is placed to keep the traction on the rubber band once the hemostat is removed. The unused portion of the band is cut off.

Fig 14.5b | A hypodermic needle is used to pre-drill a hole in the frontal bones. Then a stainless steel pin is placed transversely through the frontal sinus.

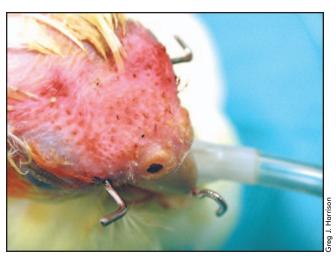

Fig 14.5d | A second bend is made in the transverse pin and a second S-shaped pin is formed and inserted in the distal rhinotheca.

Fig 14.5f | The finished traction device is in place. The extra length of the rubber bands have been cut off just above the stainless steel suture retention knot on the rubber bands. A plastic protective collar has been placed on the bird.

Fig 14.6a | A sun conure has been bitten by a larger bird. The walls of the rhinotheca are fractured and compressed into the maxillary sinus diverticulum of the infraorbital sinus.

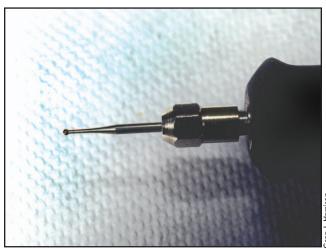

Fig 14.6b | An electric motor drill has a small shank shim replacing the larger variety. This allows the use of a small dental burr to hone out the damaged rhinotheca and bone seen in 14.6a.

Fig 14.6c | A dental burr is used to hone out the damaged tissue around the edges of the depressed slab of rhinotheca and bone.

Fig 14.6d | Microsurgical forceps grasp the slab and bone and remove it from the site to avoid a sequestration.

Fig 14.6e | The rhinal cavity mucosa was not penetrated so an absorbable layer of calcium hydroxide^a is applied as a bed for the regrowth of the bone, periosteum and rhinotheca. This layer is dried. The warm air from the electric motor can hasten this step.

Fig 14.6f | A thin layer of cyanoacrylic solvent^b is layered over the calcium layer.

Fig 14.6g | Powdered dental acrylic resin^c is sprinkled over the solvent layer, and the powder liquifies.

Fig 14.6i | The kit used to perform the procedure, 14.6 α -h.

Fig 14.8 | This gray-cheeked conure had a proximal traumatic maxillary amputation, involving the germinal area, and will likely not regrow. The conure is shown several months post-injury.

Fig 14.6h | The process has been repeated on both sides of the conure's damaged maxilla. In a couple of weeks the acrylic will dehisce and the underlying tissue continue to heal with no further attention. No antibiotics or antifungals were used pre- or post-operatively.

Fig 14.7 | A fractured mandibular symphysis has been repaired using a pair of S-shaped hooks like those used in Fig. 14.5d,e. One is placed on each side of the fracture site and the impaction bands applied. A layer of acrylic helps hold the pins and protects the fracture site.

usually with less pathogenic consequences.58 Diagnosis is by viral culture or histopathological demonstration of proliferated epithelial cells with intracytoplasmic inclusions or Bollinger bodies. No specific antiviral treatment exists but lesions can be topically debrided and treated with antimicrobials for secondary infections as deemed necessary. Systemic antibiotics and fluid therapy along with supplemental vitamin A may aid recovery.

Disinfection with lipid solvents (eg, quaternary ammonium compounds, sodium hypochlorite) and exclusion of potential insect vectors will help to stop further spread of the infection. In outbreak situations, euthanasia of severely affected birds may be carried out. Vaccines are also available for some strains.59

Avian polyomavirus (APV) has been seen to cause tubu-

lar elongation of the lower mandible in Gouldian finch (*Erythrura gouldiae*) juveniles that have survived outbreaks of the disease. ⁶⁰ These birds also exhibited delayed fledging and did not grow well. Other passerine infections with this virus have been associated with outbreaks of sudden death. ⁶¹ It has been postulated but not proven that recovered passerines may in fact become persistently infected and may shed the virus intermittently. Vertical transmission of the virus through the egg has also been postulated. ⁶¹

Parvovirus infection in ducklings reportedly caused stunted beaks with protruding tongues in survivors. 62

Primary bacterial and fungal infections of the beak are usually associated with trauma. They may cause necrosis, inflammation, hemorrhage, hyperkeratosis and the accumulation of necrotic debris with or without malodor. Cytology, culture and sensitivity are required to diagnose these infections.

Cryptococcosis has been associated with proliferative masses causing disruption of the nares, rhamphotheca and deeper beak and sinus structures in several psittacine species. 63,65 In some cases these lesions may be mistaken for neoplasms. They are characterized by gelatinous exudates which, when stained, contain large oval budding yeasts (4 to $7 \mu m$) surrounded by a capsule 2 to 4 times the diameter of the cell. 64,65 Gram's stain, India ink, and Wright's stain have all been used to diagnose this infection cytologically. It can also be easily cultured on Sabouraud- dextrose agar. There is usually little surrounding inflammation, restricted to mild numbers of epithelioid macrophages, multinucleated giant cells and heterophils. Cryptococcus neoformans var. neoformans has a worldwide distribution, grows poorly at temperatures over 40° C and hence rarely causes problems in birds. It is commonly found in pigeon droppings. C. neoformans var. gattii is restricted to river red gums (Eucalyptus camaldulensis) and forest red gums (E. tereticornis) and grows poorly above 37° C and is most commonly identified in avian infections. 63 Treatments such as fluconazole orally at 8 mg/kg/day for at least two months, ketoconazole at 2 mg/kg BID per os gradually increased to 25 mg/kg bid per os and surgery to debulk the proliferative masses have all been suggested. 63-65 However, recurrence of lesions weeks to months after treatment is common, with early detection and aggressive therapy most likely to yield favorable results. Cryptococcosis is a potential zoonotic infection so public health issues need to be considered before treatment is instituted.

Fungal infections causing beak necrosis in Gouldian finches (*Erythrura gouldiae*) have also been described. Affected birds had rhamphothecas that were characterized by a flaky white or yellow appearance. Fungal

Fig 14.9 | Knemidocoptes mites and gross over-growth of the beak.

hyphae were detected in the beak matrix but no species identification was presented.

Knemidocoptes spp. mites can cause proliferation and inflammation of the psittacine beak (Fig 14.9) and are commonly seen in budgerigars, particularly young or immunosuppressed birds. Close inspection reveals the characteristic honeycomb patterning resulting from the mites tunneling into the skin. In chronic lesions, the germinal layer of the rhinothecal and gnathothecal epithelium can be so disrupted that permanent beak deformities result. Diagnosis is by way of skin scrapings. Treatment is simple with ivermectin/moxidectin, topical ectoparaciticides or even paraffin oil over the lesion that suffocates the mites being successful. Spiruroid (Oxyspirura spp.) infections in cranes have also been linked to beak deformities, as has trichomoniasis in cockatiels.⁴⁴

Mycotoxins from *Fusarium* spp. in moldy food have resulted in beak deformities in poultry.³²

Neoplasia

A number of neoplasms involving the beak have been described. Fibrosarcomas are considered the most common neoplasms of the beak, whilst squamous cell carcinomas and malignant melanomas are also seen. They cause distortion of the beak and surrounding tissue. Cytology of fine needle aspirates or histopathology on biopsy specimens provide a diagnosis, give information as to the likelihood of success with surgical debulking or chemotherapy and provide a prognosis for the patient. 57,66

DISEASES OF THE OROPHARYNX AND ITS STRUCTURES

Diseases of the oropharynx are characterized by anorexia, dysphagia, halitosis, gaping, rubbing of the

beak or more generalized signs of ill thrift such as lethargy and disheveled plumage. Direct visual examination of the oral cavity under illumination will reveal most lesions, especially if magnification is used. This can be done with the patient awake or under general anesthesia. Further magnification in difficult to examine places can be achieved via endoscopy. Offending lesions can be swabbed or biopsied and the material obtained can be stained on slides, cultured or sent for cytological or histological examination.

Infectious Causes

Various viral infections have been found to infect the avian oropharynx. As mentioned previously, poxvirus can cause proliferative caseous lesions in the mouth and esophagus. Pigeon herpesvirus (PHV-1) can cause mucosal ulceration and diphtheritic membrane formation in the oropharynx, cere or beak commissure as part of the overall infection. 44,67 It affects young birds and the immunosuppressed most severely and should be suspected in flocks that suffer repeated bouts of trichomoniasis that are difficult to control. Spread is via fecal and pharyngeal secretions, and latent carriers are important reservoirs of infection.⁶⁷ Diagnosis is presumptively based on the presence of basophilic and eosinophilic intranuclear inclusion bodies seen on histology or cytology of affected tissue, particularly epithelial cells. Virus isolation and neutralizing antibody techniques are also available.

Abscesses and micro abscesses, plaques and granulomas are consistent with a number of diseases including viral, bacterial, yeast and parasitic infections, hypovitaminosis A and even chemical burns. Bacterial infections in the mouth can be caused by a variety of bacteria. Some of the more frequently isolated pathogens include *Staphylococcus* spp., *E. coli*, *Klebsiella* spp., *Pseudomonas aeruginosa* and other gram-negative bacteria. ^{37,44,68} The lesions may be localized or cause a generalized stomatitis and are usually secondary to oropharyngeal trauma, other infectious diseases or other causes of immunosuppression. Treatment should include systemic antibiotics based on culture and sensitivity results, local debridement, supportive care, identification and, where possible, correction of underlying immunosuppressive factors.

Mycobacterial granulomas may sometimes be seen in the mouth, though they are more commonly associated with lesions in the intestinal tract and liver and other intracoelomic organs. Fine needle aspirates of lesions and acid-fast staining may reveal the presence of the mycobacterial organisms within macrophages. Where possible, cultures to speciate the type of mycobacteria should be carried out, although recently PCR testing that gives more rapid results has become available. Hematology is characterized by a very high leukocytosis, often with a

monocytosis. Mycobacterium genavense has recently been recognized as the causative agent in many avian infections that were previously attributed to M. avium subsp avium. 70,71 M. tuberculosis has only infrequently been responsible for disease in birds, even though it is the primary cause of tuberculosis in people.72 Mycobacteriosis is a chronic debilitating disease with the potential for zoonotic spread, particularly in the immunosuppressed person.72 Therefore the decision to treat or to euthanize is an important consideration. Multiple drug therapy is essential if treatment is to be attempted due to the high level of resistance to any single antimicrobial. Several treatment modalities based on human trials have been suggested. 73,74 Currently the combination of clarithromycin, ethambutol and rifabutin is the treatment of choice in humans and has been used with enrofloxacin in psittacines with success (see Chapter 28, Implication of Mycobacteria in Clinical Disorders).74

Candidiasis is a very common cause of stomatitis in birds, particularly in young, immunosuppressed birds, those on antibiotics and in lorikeets because of the high sugar content of some nectar mixes. The causative agent is usually Candida albicans, although other species may be involved. It is opportunistic and can be a primary or secondary pathogen. It causes white oral plaques with a caseous exudate. It is easily cultured and, when smears of lesions are made, the characteristic budding spores may be seen. Gram's stain, Diff-Quik and new methylene blue stains may help visualization. Histopathology is required to confirm that the yeast is causing the infection, however the presence of large numbers of budding yeasts or the presence of hyphal forms is suggestive. Treatment may be topical and/or systemic. Mild infections may respond to oral nystatin at 300,000 IU/Kg orally twice daily and/or topical chlorhexidine or oral miconazole formulations. More severe infections may require systemic antifungal therapy such as ketoconazole (10 to 30 mg/kg orally twice daily), fluconazole (20 mg/kg orally every 48 hours),75 flucytosine at 250 mg/kg orally twice daily for 14 to 17 days or itraconazole (10 mg/kg orally twice daily for 21 days).76

Parasites are another cause of oropharyngeal pathology. *Capillaria* spp. are the most common nematode in the upper gastrointestinal tract. They may cause oral inflammatory masses, diphtheritic oral lesions or hemorrhagic inflammation of the commisure of the beak.⁷⁵ They are more commonly found in the small intestine.⁷⁷ They parasitize most species of birds including psittacines, passerines, columbiforms, gallinaceous birds and raptors.^{77,78} Affected birds exhibit head flicking, dysphagia, weight loss and diarrhea. The adult parasites are very thin and can be difficult to see, but may be found in smears of lesions, as may their characteristic bi-opercu-

lated ova. Ova may also be detected upon fecal floatation, but they are intermittent shedders of ova and produce less than most ascarids. Their life cycle can be direct or indirect using earthworms as intermediate hosts.77 They can be quite resistant to anthelmintics so high doses may need to be instituted. Examples include benzimidazoles (fenbendazole 100 mg/kg once or 25 mg/kg daily for 5 days, oxfendazole 10 mg/kg,) levamisole (40 mg/kg, beware of narrow safety margin); moxidectin 200 μ g/kg (used up to 800 μ g/kg by this author). 77,78 Ivermectin at standard doses (200 µg/kg) has been ineffective.78 Benzimidazole or levamisole treatments should be repeated in 14 days. Environmental hygiene to prevent reinfection and removing potential intermediate hosts are all important control measures.

Spiruroids have been diagnosed in raptors, corvids and other species, and may cause raised granulomatous reactions in the mouth and crop. The worms, or their thick-walled embryonated eggs, may be found in oral, crop or fecal samples. Treatments include oral dosing with moxidectin⁷⁷ and/or manual removal of adults. *Contracaecum* spp. have been associated with severe oral infections in young piscivorous birds, particularly pelicans.⁴⁴ In birds of prey, *Synhimanthus falconis* has been reported in the oropharynx⁴⁴ and *Serratospiculum amaculatum*, a parasite of the air sacs, can cause diphtheritic lesions of the oropharynx, which need to be differentiated from those caused by trichomoniasis.^{77,79,80} Their eggs can be found in oral mucus or in feces.

Trichomoniasis is commonly found in pigeons, budgerigars and raptors and is occasionally seen in other species such as cockatiels, Amazon parrots, conures, canaries and zebra finches. 44,79 The causative organism, usually Trichomonas gallinae, can exist as different strains with different pathogenicities. In pigeons and raptors, white or yellow caseated plaques may be seen in the oral cavity. These usually extend to the crop and esophagus and may go as far as the proventriculus. These plaques may need to be differentiated from other diseases such as candidiasis and poxvirus infection. Budgies usually show no oral lesions. Affected birds usually exhibit regurgitation, dysphagia, weight loss, listlessness, palpable mucous in the oropharynx and crop and, in severe cases, vomiting blood and death. In pigeons the disease may be generalized, infecting the liver, umbilicus and cloaca, especially in squabs. Diagnosis is via wet mount examination of oral lesions or crop fluid, revealing the motile flagellated organism under high power magnification. Warming samples increases protozoan activity. The life cycle is by direct oral contact between birds, and spread through common drinking water is also important. Raptors are

thought to acquire infection through ingestion of infected pigeons. However, freezing carcasses has proven not to work (S. Hudelson, personal communication, 2004). Carrier states exist and are thought to be responsible for reinfecting flock mates. Such birds should be culled. Treatments suggested include ronidazole (6 to 10 mg/kg once daily for 7 to 14 days), dimetridazole (100 to 400 mg/L drinking water), metronidazole (20 to 50 mg/kg twice daily) and carnidazole (20 to 30 mg/kg once).75,77,78,81 A dose of 50 mg of carnidazole has been reported to be most effective (S. Hudelson, personal communication, 2004). Note that dimetridazole has a low safety margin and should be avoided in hot weather, during breeding or when racing pigeons. Diphtheritic plaques may need to be removed by debridement. Antibiotics for secondary infections may also be required.⁶⁸ Regular monitoring of flocks for infection is recommended in pigeons and budgerigars.

Nutritional Causes

Hypovitaminosis A can lead to squamous metaplasia of the oropharyngeal epithelium, particularly glandular epithelium, leading to plaque and granuloma formation. 44,75,82 In psittacines, this typically involves the submandibular or lingual salivary glands. Sometimes affected birds exhibit a subcutaneous swelling caudal to the mandible. The choanal papillae are often shortened and stunted. If severely damaged, the choanal papillae fail to regenerate, so caution is warranted when using this sign for diagnosis. Affected birds typically have a history of being fed a predominately seed-based diet. Dietary correction via parenteral vitamin A supplementation or use of reputable formulated diets is needed. Some granulomas may be excised surgically. Secondary bacterial infections may be found and should be treated as required. In gallinaceous birds, lesions are confined to the mucous glands of the pharynx and their ducts. Keratinization of the glandular epithelium causes blockage of duct openings, hence secretions and necrotic debris accumulate. These appear as small white hyperkeratotic lesions (see Chapter 4, Nutritional Considerations).

Traumatic Causes

Traumatic injuries can occur in the oropharynx due to fighting or accidental trauma. Injuries of the psittacine tongue are common due to its frequent use as a probing and sensing organ. Tongues are very vascular, and in psittacines well muscled, so control of bleeding is a first priority. This may involve the use of electrocautery or suturing. The birds may easily remove sutures. Some authors have found the need to wire the beak closed to prevent suture removal.⁷⁵ In this case a pharyngostomy tube may need to be placed until the wound heals. Caustic injuries can be caused by the ingestion of certain

chemicals, for example silver nitrate cautery sticks, access to excessively hot foods or ingestion of trichotecenes, especially T2 toxin.44 These often cause anorexia and dysphagia due to the pain experienced. Analgesia may be of added benefit in these cases, as well as supportive care (pharyngostomy feeding, fluids, antibiotics) until healing is complete. Foreign bodies including wire, wood and plastic have also been known to cause penetrating wounds.

Neoplastic Causes

Neoplastic diseases of the oral cavity have been documented and include epithelial and mesenchymal tumors.⁵⁷ The most common problem seen in new world psittacines is oral papillomatosis. Lesions range from mild mucosal roughening to overt verrucous masses. They can also be found in the crop, esophagus, proventriculus, and cloaca and have been associated with bile duct carcinomas. Severe lesions can ulcerate, hemorrhage or cause gastrointestinal or distal reproductive tract obstruction. Their exact cause is unknown. Although histologically the lesions appear similar to those of mammalian papillomaviruses, there is no immunohistochemical or DNA evidence to support the presence of an avian papilloma virus. Instead, herpesvirus is consistently being detected in these papillomatous lesions.83 True parrot papillomavirus has been reported in only one African grey parrot.84 Squamous cell carcinomas, fibrosarcomas and lymphosarcomas have also been reported.85 They can be quite painful and cause inappetence. Diagnosis is based on biopsy and histological examination.

DISEASES OF THE ESOPHAGUS AND CROP

Many of the diseases found in the oropharynx are, not surprisingly, also found in the esophagus and crop. The esophagus can be injured as a result of tube-feeding (Figs 14.10a-c).

Infections

Viral infections such as poxvirus and herpesvirus have been reported. Proventricular dilatation disease (PDD), of suspected viral origin, may also affect the crop but will be more fully discussed later. Bacterial infections, both primary and secondary, are commonly seen with crop diseases. In mild infections, there may be bacterial growth and mucosal colonization with little inflammatory response. Severe infections, however, are characterized by hemorrhage, necrosis and sometimes fibrinopurulent exudates of the mucosal surface.57

Typically, crop motility is impaired with delayed crop emptying and regurgitation. Birds can quickly become

Fig 14.10a | Tubefeeding a sick bird is a frequent event in an avian veterinary facility. The round ball tipped needles can make the job easier for one person.

Fig 14.10b | The clear delicate esophagus can be palpated for the tube presence or visualized by wetting the right ventral-lateral cervical area. The ball is easily seen through the transparent esophagus and skin of the neck in small thin birds.

Fig 14.10c | A similar feeding tube in a lovebird with a hemotoma in the crop area from trauma resulting from bruising that can occur from improper restraint and flailing when a bird is being tubed. Although this is very uncommon, it is even less likely to occur if a speculum and a soft catheter are used.

Fig 14.11a | A crop burn, usually in a handfeeding baby that is fed scalding food heated by a microwave oven. The area is soft and friable and is best allowed to form a scab prior to any surgery.

Fig 14.11b | Several days after becoming a dark, hard scab the burnt area will open allowing food to fall from the crop. Topical acrylic glues can expand the time the scab is retained and often can be kept in place long enough for the damage to completely heal, avoiding surgery completely.

listless, toxemic, dehydrated and, if untreated, die. Yeast infections may also be involved, and the organisms are typical of *Candida* spp. infections. *Candida* spp. has also been described as a primary crop pathogen in some species, namely lovebirds (*Agapornis* spp.) and cockatiels. As well as the clinical signs listed above, a palpably thickened crop wall may be found. Causative organisms can be diagnosed via examination of wet and stained smears obtained via crop washes and culture and sensitivity. Treatment involves the use of oral topical and/or systemic antifungals, crop washes, antiemetics and fluid therapy. Predisposing management factors need to be addressed, particularly in hand-reared birds.

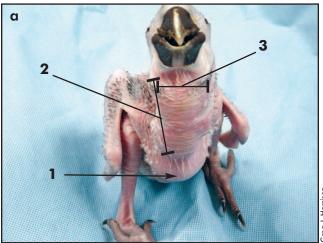

A large number of endoparasites are known to infect the crop. The most familiar parasitic disease of the crop is trichomoniasis, which was discussed previously. A host of nematodes and trematodes can also be found in the crop and esophagus. As well as *Capillaria* spp. already mentioned, *Echinura uncinata*, *Gongylonema ingluvicola* (quail and gallinaceous birds) and *Dispharynx nasuata* have all been found to invade the crop esophageal mucosa. 44.77

Noninfectious Diseases

Primary non-infectious diseases of this region include crop burns, foreign body penetration, lacerations and impactions, hypovitaminosis A and ingluvioliths. Excessively hot feeding formulas may lead to full thickness burns of the crop and skin in hand-reared chicks and occasionally in adults. The burns usually occur in the anteroventral region of the crop. Initially the area may appear just dry, but subsequently reddening and edema may occur, followed by blistering and often necrosis (Figs 14.11a,b). This process may take several

days. The dehisced wound, which is externally visible, allows food to fall out of the crop as the chick is fed. Treatment involves addressing any dehydration and infection problems. It may be best to manage this condition medically for the first 3 to 5 days to allow the burn to scab over and fully fistulate before surgery is attempted. Premature surgical closure usually results in wound dehiscence due to continued necrosis of the surrounding skin that may not have been noticeable at the time of initial surgery. Surgery involves anesthesia and debridement of the affected area, removing all dead and discolored tissue, and closure of the deficit in at least two layers, ensuring that the crop and skin are closed separately. Beware of reduced crop capacity immediately post-surgery, until healing and crop expansion can occur (see Chapter 35, Surgical Resolution of Soft Tissue Disorders).87 Other causes of crop trauma such as forceful use of feeding/medicating tubes, bite wounds or foreign bodies can be similarly treated. Caution — food traumatically placed subcutaneously or within the neck structures must be flushed and debrided immediately in the event feeding has caused a rent — let heal by secondary intention healing (Figs 14.12a-f).

Ingluvial foreign bodies include food items, grasses, wood, metal and plastic items usually accidentally ingested by birds. In hand-reared chicks, plastic feeding tubes can come loose and be accidentally swallowed during the vigorous head pumping which birds may do during feeding. Diagnosing these problems is via history, crop/esophageal palpation, radiography (both plain and contrast) or endoscopy. The offending items can be removed manually, endoscopically or surgically via an ingluviotomy. Impactions of the crop frequently occur as a result of a sudden change of food. In ducks and poultry

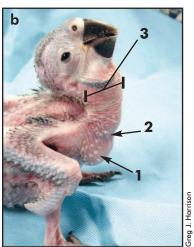

Fig 14.12a,b | A baby macaw an hour after having hand-feeding formula traumatically introduced into the cervical neck tissues. This injury occurs from using a syringe for feeding. Macaws "pump" hard and if the head is not controlled the syringe tip can penetrate the pharyngeal tissues resulting in food being deposited into the cervical tissue. Edema and some hemorrhage also adds to the swelling. The food must be flushed out within hours, or septicemia may be rapid and overwhelming. 1. A normal crop with some food present. 2. Vertical swelling from food deposited into tissues. 3. Horizontal swelling of tissues.

Fig 14.12c | An incision over the food swelling — avoiding the esophagus, crop and vascular structures of the cervical region.

Fig 14.12d | The incision has reached the pocketed food and it spills out.

Fig 14.12e | A cotton-tipped wood applicator enters the oral penetration wound and exits the neck incision. The cotton tip is grasped with a forcep and the forcep is pulled up and out through the mouth. A cut rubber band is grasped by the forcep and pulled out of the incision and tied in place to act as a seton to allow flushing for 2 days.

Fig 14.12f | Rubber band seton tied in place. Flushing of the wound QID with Normosol®, and a tissue disinfectant is performed. Antibiotics and antifungals are administered in a hand feeding formula that is fed via a silicone tube to assure the food gets into the crop.

Greg J. H

it has been associated with sudden access to lush grasses and sprouted grains.⁴⁴ In caged birds, *ad libitum* supply of grit has been associated with crop impactions and, on occasions, this has resulted from the overzealous feeding of grit to chicks.⁸⁸ In raptors it is associated with the sudden availability of roughage in a previously low-roughage diet. Diagnosis and treatment are as described for foreign bodies.

Ingluvioliths are various mineral concretions that occasionally develop in the crops of some birds, particularly budgerigars. Calculi consisting of urates surrounding seed husks, potassium phosphate, oxalate and cystine have been described. The exact cause of these is not known, but it is speculated that birds that have experienced periods of starvation may have been forced to eat seed husks and urates. ⁴⁴ In some instances these calculi become large enough that they need to be removed. This can be achieved via endoscopy or ingluviotomy.

As well as the neoplasms mentioned in the oropharynx, the crop and esophagus could suffer from tumors of smooth muscle origin such as leiomyomas and leiomyosarcomas. Although asymptomatic when small, they can become very large, necrotic and hemorrhagic. They are characterized microscopically by interlacing bundles of fusiform cells with moderate amounts of cytoplasm.⁵⁷ Carcinomas of the submucosal glands also occur. They are often large, sometimes necrotic and hemorrhagic, and involve much of the esophageal or crop wall with invasion into surrounding tissue.⁵⁷

Crop Stasis

Crop stasis or "sour crop" is a clinical sign of disease, and not a disease in itself. Clinical signs include regurgitation, delayed crop emptying, a sour odor, inappetence, dehydration, anorexia and listlessness.87 "Sour crop" is usually complicated by bacterial and or fungal infection that may be primary, but is more often secondary. Crop stasis is most often seen in hand-reared chicks and results from poor management. Food fed at the wrong temperature or consistency, not allowing the crop to empty between feedings, poor hygiene, incorrect incubation temperatures and humidity and concurrent disease are all examples of possible causes of crop stasis in chicks. In adults, the condition can result from various crop infections, systemic or metabolic disease, heavy metal toxicity, foreign body ingestion or even PDD. Normal psittacine crop floras include few gram-positive bacteria and scant non-budding yeasts. Treatment of this condition involves identifying and treating the underlying disease, as well as crop flushes with mild antiseptic solutions, antimicrobial therapy as appropriate and supportive fluid therapy. See Chapter 7 Emergency and Critical Care.

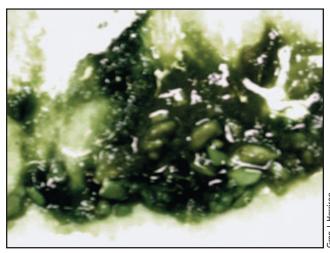

Fig 14.13 | The passing of whole seeds is characteristic of gastrointestinal disease. Many causes such as lead, parasites, PDD and pancreatitis are possible.

DISEASES OF THE PROVENTRICULUS AND VENTRICULUS

Diseases of the proventriculus and ventriculus can have varying clinical signs ranging from regurgitation, weight loss, appetite changes (either anorexia or polyphagia), undigested seed in the feces (Fig 14.13) and lethargy. Most diseases of these organs produce similar clinical signs that make their identification more challenging.

Infectious

Perhaps the most common gastrointestinal disease is proventricular dilatation disease (PDD). The suspected cause is a virus. It has been diagnosed in over 50 species of psittacines, but also in several other avian species including Canada geese, canaries, weavers, toucans, spoonbills and honeycreepers.89 It is characterized by a lymphoplasmacytic infiltration of peripheral and central nerve tissue. It commonly affects the myenteric plexuses supplying the gastrointestinal tract, resulting in atrophy of the smooth muscles of the crop, proventriculus, ventriculus or small intestine. This causes delayed gastrointestinal motility and organ dilatation. It can also affect the Purkinje cells of the heart, the adrenal medulla, the brain and the spinal cord. The lesions can be very segmental which may explain the variation in clinical signs seen.90

Gastrointestinal clinical signs include progressive weight loss, regurgitation, crop impaction, passage of undigested food and eventually death, usually within 12 months. An 80 to 120 nm enveloped virus has occasionally been isolated from infected birds and has been used experimentally to induce infection in some birds. A virus is certainly suspected but not proven. The virus itself may not be the cause of the disease; however the inflammatory response may be. However, its exact identity

is unknown at the time of writing. Diagnosis is based on finding lymphoplasmacytic infiltrates in ganglia and associated nerves of the myenteric plexus of the gastrointestinal tract. 90,91 However, given the segmental nature of the disease, it is difficult to know which area of myenteric plexus to biopsy. Thus, a positive biopsy is diagnostic but a negative biopsy does not rule out the disease. 90 The crop is considered the safest area from which biopsies can be taken. Biopsy sections should contain blood vessels, as these are most likely to contain nerve tissue. The proventriculus has a thin wall and acid secreting glands which make it a risky choice for biopsy. Similarly, ventricular biopsies are not recommended, as there is real risk of damaging the myenteric plexus.

Large amounts of the suspect virus are shed by infected birds and transmission is proposed to occur via the fecal-oral route.⁹¹ The virus is fragile in the environment and, hence, hygiene and management are vital in preventing spread of infection. The virus's environmental fragility may explain why epornitics occur more commonly in indoor aviaries rather than outdoor collections. Although many birds eventually die from this disease, some chronically infected parrots have been detected which have lived for years, intermittently shedding the virus. These may be reservoirs for reinfection in aviary situations. Although there is no cure for the disease, celecoxib, a Cox-2 NSAID, has been used to improve clinical signs by decreasing the inflammatory reaction around affected nerves.92 The dose given was 10 mg/kg orally every 24 hours for 6 to 24 weeks. Improvement in clinical signs occurred in 7 to 14 days. Treatment was ceased once birds resumed normal body weight, condition and diet. The longest survivor reported was a blue and gold macaw (Ara ararauna) that finished therapy two years previously and remained in normal physical condition, eating a normal diet and had no radiographic signs of PDD and was negative on biopsy. However, no comment was made as to whether virus particles continued to be shed in its stools.

Macrorhabdus, previously known as avian gastric yeast (AGY) or megabacteria, have been reported to infect a large range of pet and wild birds (see Chapter 30, Implications of Macrorhabdus in Clinical Disorders).

Bacterial infections in the proventriculus and ventriculus can be primary but are usually secondary to other immunosuppressive or disease states. The organisms most often associated with disease are gram negative and include *E. coli*, *Klebsiella* spp., *Salmonella* spp. and *Enterobacter* spp. ⁸⁵ These often affect the intestine, thus giving clinical signs including diarrhea, maldigestion/malabsorption, anorexia and weight loss. Diagnosis

is based on culture, with fecal cultures often taken. Fecal Gram's stain may also show gram-negative overgrowth. *Candida* spp. infiltrating the proventricular and ventricular wall have also been documented, particularly in finches. Treatments as outlined earlier, optimal nutrition, hygiene and correcting predisposing stressors are all important management tools.

A number of nematodes have been diagnosed in the avian proventriculus. Echinura uncinata, Gongylonema spp., Cyrnea spp., Tetrameres spp. and Dyspharynx nasuata have all been found. Ventricular parasites include Amidostomum spp., Cheilospirura spp., *Epomidiostomum* spp. and *Acuaria* spp. 44,77 Of these, Acuaria spp. appear to be the most commonly encountered. They are commonly found to infect finches, but galliforms are also susceptible. These "gizzard worms" are fine and hair-like and burrow just under the koilin lining of the ventriculus, impairing gizzard function and digestion of food. Affected birds usually exhibit ill thrift, may have undigested seed in the droppings and die. Secondary bacterial infections further complicate the infection. The life cycle is indirect, so removal of insects from the environment is important. Anthelmintics such as ivermectin, moxidectin, benzimidazoles and levamisole have all been used with varying degrees of success.77

Cryptosporidiosis is a protozoal disease usually seen to infect the intestine of immunosuppressed animals, including birds. In finches, however, it has a predilection for the proventriculus, where it causes necrosis and hyperplasia of glandular epithelial cells.¹¹³ Finch isolates are different genetically from other species and may represent a unique species of *Cryptosporidium*.¹¹⁴ Affected birds show decreasing body weight and yellowish droppings which may contain undigested seed. Azithromycin, roxithromycin, toltrazuril and paromomycin have met with some success as treatments.¹¹³ Underlying immunosuppressive diseases or environmental stressors need to be identified and corrected.

Non-infectious

Proventricular or ventricular foreign bodies are more commonly encountered in ratites, galliforms and waterfowl, but are also seen in psittacines and other species. Psittacine chicks which ingest indigestible fabric fibers or bedding material such as ground corncob, kitty litter, crushed nut shells, shredded paper, styrofoam, grit, plastic, rubber or wood shavings may develop proventricular/ventricular impactions. 44,75 In older parrots, these same items plus other cage or household items may be ingested. In flightless birds, and in particular ostriches, exposure of birds to a new substrate may predispose

them to proventricular/ventricular impaction. Other illnesses may lead to a depressed appetite or pica. 115

Affected birds classically have poor appetites, pass scant feces, exhibit regurgitation especially if force-fed, and are depressed and lethargic. Diagnosis is via radiography, endoscopy, palpation (in larger species) or exploratory laparotomy. Where nails or other ferric compounds are suspected, this author has also seen metal detectors successfully used. Fiber will only show up on gastroscopy (Fig 14.15).

Treatment depends on the severity of the impaction, or the nature of the foreign body ingested. If the bird is bright, the impaction is not complete and the offending item is capable of being passed by the bird, then medical treatment may be adequate. This may include supportive fluid therapy and antibiotics, the administration of psyllium (beware in cockatiels) or paraffin liquid and force-feeding with easily assimilated high-energy soft foods. Metoclopramide may help stimulate small intestinal motility and thus assist in ventricular/proventricular emptying. Prevention of access to the offending items is also necessary. Attempts should be made to identify underlying disease states that have a bearing on the final outcome.

Some items may be able to be removed endoscopically. This can be done through the mouth or via an ingluviotomy. In the ostrich, a technique of proventricular flushing is described. 116 With the bird held firmly above the tarsus, it is turned upside down, its glottis closed and a hose connected to a steady stream of water is passed from the mouth to the proventriculus. Massaging the proventriculus helps to loosen the impaction. The loosened material often passes out the mouth with the hose in situ. This is repeated until clean water passes out the mouth. Needless to say, this procedure requires considerable manpower but is useful where general anesthesia is not an option and medical therapy has failed. In many cases, however, surgery is indicated to relieve the impaction or remove the foreign body. These techniques have been described elsewhere. 115,117

Heavy metal toxicities can also lead to gastrointestinal, renal and CNS signs as part of their pathophysiology. Psittacines in particular fall victim to inadvertent acute lead and zinc intoxication due to their curious nature and penchant for chewing any object they may find. Items varying from galvanized cage wire to paint, curtain weights, stained glass windows, jewelry, coins, wine bottle foil, toys and mirror backing are possible sources for these heavy metals. Waterfowl ingest lead shot whilst feeding, mistaking it for gravel. Falcons ingest lead by eating prey that has been shot. The ingested heavy metal pieces are acted on by the acidic content of the proven-

triculus and macerated by the ventriculus leading to rapid absorption. The mucosal linings become very irritated, and in severe cases, the ventricular koilin may be damaged. Pancreatic damage may also be a result of zinc toxicosis. Affected birds may show variable clinical signs which include inappetence, decreased fecal volume, regurgitation and vomiting, ileus, green diarrhea, polyuria, polydypsia, CNS signs (particularly with lead poisoning) and feather picking. 118,120 Lead poisoning in waterfowl causes weight loss, limb and neck weakness, and bright green feces. 119 A tentative diagnosis is based on a suggestive history, clinical signs and the presence of radiodense particles within the gastrointestinal tract on survey radiographs. However, the client is often unaware of exposure to heavy metals, the clinical signs are nonspecific and the heavy metal is not visible on radiographs. Definitive diagnosis is based on the presence of elevated blood lead or zinc levels. 90,118, 121,122 Elevated levels of amylase, CPK and uric acid may be found with zinc intoxication. 120 The acute cases respond well to chelation therapy with edetate calcium disodium (EDTA) at 30 to 50 mg/kg once to four times daily by intramuscular or intravenous injection, depending on the severity of signs and amount of heavy metal ingested. 90,120-122 Other chelating agents such as penicillamine given orally at 55 mg/kg twice daily can be used in conjunction with CaEDTA.¹¹⁸ Succimer is the preferred oral lead chelator at 25 to 35 mg/kg orally twice daily.81,118 Concurrent parenteral fluid therapy is essential for rehydration and assisting excretion of the metals. Where gastrointestinal function permits, gavaging of high energy/electrolyte fluids and lubricants such as mineral oil, peanut butter, psyllium, magnesium sulphate or sodium sulphate have all been suggested. These products have been found to be ineffective in waterfowl. 118 Antibiotics for secondary bacterial infections can be given and antiemetics and intestinal prokinetic agents (eg. metoclopramide) may also be helpful. If possible, the offending particles should be removed via endoscopy or ingluviotomy/gastroscopy. Particles that have a ferrous or iron base can also be removed by inserting a feeding catheter equipped with powerful neodymium-ferro-borium alloy magnets (Fig 14.14).44 Pure lead, zinc, or many of their alloys cannot be removed with a magnet. It should be remembered that lead is not normally found in animals, as it is not involved in any normal biochemical pathway. 118,122 It also accumulates in the body over time. Zinc on the other hand is an essential trace metal and so needed in low levels. It is not stored in the body over time but is excreted. 118,121 Chronic zinc toxicities are thus due to continued or repeated exposure.

Ulceration of the proventriculus occurs occasionally in pet birds but more commonly in flightless birds secondary to foreign body ingestion or disease states. No common

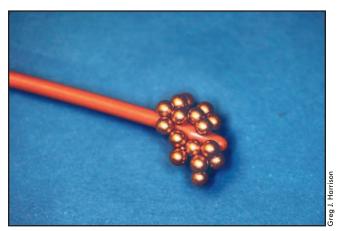

Fig 14.14 | A set of magnets installed in the end of a rubber catheter that have attached to copper coated ferrous shot. This device can be used to remove ferrous metals, some of which can be galvanized and thus contain zinc and/or lead in toxic amounts.

Fig 14.15 | Nylon fiber retrieved from the proventriculus of a cockatiel on a seed diet that was allowed to pull apart a nylon carpet.

etiologic agent has been identified, but a link has been suggested between chronically stressful environments and the occurrence of proventricular ulcers.90 Ulceration may also be secondary to zinc toxicity.85,121 Clinical signs are non-specific but may include anorexia, regurgitation, gastrointestinal pain, lethargy and melena. Once an ulcer perforates, most birds will die from sepsis and shock within 6 to twelve hours.90 Thus, early detection of an ulcer is imperative but can be difficult. Gastroscopy should be considered in any patient with persistent signs of gastrointestinal pain or melena. Some of the human rapid tests for melena are useful for detecting the presence of digested blood in the feces of seed eating birds.*

*Eds. Note: some debate continues on the specificity of such tests.

There is a report of proventricular obstruction in an adult male eclectus parrot caused by a tubular diverticulum of the ventriculus. 123 This diverticulum consisted of dysplastic koilin and smooth muscle and caused complete obstruction of proventricular outflow. No inflammation, organisms or neoplastic changes were associated with the lesion. The cause was undetermined.

Neoplasms of the proventriculus and ventriculus are seen in a number of species, particularly in budgerigars and grey-cheeked (Brotogeris pyrrhopterus) and Amazon parrots. Proventricular carcinomas are most commonly found at the isthmus and are usually flat rather than nodular.124 They are invasive, often extending through the muscular layers and may reach the ventricular wall and serosa. 57,125 However, they rarely metastasize. 125 Clinical signs may include anorexia, regurgitation, weight loss, maldigestion and melena. Papillomas may occur as discussed previously and smooth muscle tumors are uncommon.57

Surgery of the gastrointestinal tract is discussed in Chapter 35, Surgical Resolution of Soft Tissue Disorders.

DISEASES OF THE INTESTINES AND PANCREAS

Intestinal tract disorders usually manifest themselves clinically as changes in the color, bulk and nature of the feces produced. Thus, diarrhea, maldigestion, voluminous droppings and/or melena may be evident in affected birds. Anorexia, depression and weight loss often accompany these enteric signs.

Infectious

The majority of intestinal pathology is at least in part attributable to infectious agents. By far the most common cause of diarrhea in pet birds is due to bacterial infections, although these are seen less commonly in adult raptors. 57,78,90 Gram-negative bacteria are most commonly implicated. Enterobacteriacae are most frequently isolated including E. coli, Salmonella spp., Klebsiella sp., Yersinia sp., Pseudomonas aeruginosa and Proteus sp.90 They can be both primary and secondary pathogens. The gross lesions induced in the affected intestine include redness, exudation and occasionally ulceration. Histologically, necrosis, fibrin deposition and predominately heterophilic infiltrates are noted,⁵⁷ although the bacteria may not always be present in all lesions.

Gram-positive bacteria have also been responsible for intestinal disease. Enterococcus birae has caused enteritis and septicemia in 10 psittacine species. 126 Campylobacter spp. especially C. jejuni has been associated with yellowish diarrhea and enteritis in many avian species including psittacines,85 passerines, waterfowl, galliformes¹⁰⁷ and ostriches. ¹²⁷ Affected birds, which are often young, exhibit lethargy, anorexia, diarrhea and emaciation. Erythromycin and tetracyclines are the frontline

treatments for this bacterium. 107 Clostridial infections have also been diagnosed in many avian species and are known for their ability to produce potent toxins. 107 Clostridium perfringens can cause necrotic enteritis and foul-smelling feces in psittacines, ostriches, 127 and other species. C. tertium has been reported in a cockatoo with megacolon and chronic, foul-smelling diarrhea. This resulted in severe dilation of the colon characterized by a lymphoplasmacytic inflammatory reaction. The sporulated form of this bacterium has a "safety-pin" appearance that is quite visible under Gram's stain (see Chapter 4, Nutritional Considerations, Section II, Nutritional Disorders). Anaerobic culture yields a definitive diagnosis. Treatment involves the use of metronidazole (25 mg/kg orally twice daily)⁷⁵ or clindamycin (100 mg/kg orally once daily).81,107

Mycobacteriosis is typically a chronic wasting infection in birds, primarily affecting the gastrointestinal tract rather than the respiratory tract, as is the case with mammals. Most avian species are susceptible. Waterfowl, flightless birds, grey-cheeked parakeets, older Amazon and Pionus parrots, budgerigars, siskins, Gouldian finches, toucans and pigeons are particularly susceptible. 69,75 It is particularly a problem where birds are congregated. The intestine appears to be the primary site affected. The submucosa becomes infiltrated with large numbers of histiocytes that contain many acid-fast organisms. This affects the bowel's ability to digest and absorb ingesta. Other granulomatous lesions may be found in the liver and spleen, the bone marrow and the respiratory tract. In other cases, only skin lesions are noted. The course of this disease may take years.

Primary mycotic intestinal infections are rare, but secondary invasion by *Candida* spp. or *Zygomycetes* spp. are sometimes seen.⁵⁷

Viral diseases can cause severe disease to the intestine. PDD can cause segmental damage to the intestinal smooth muscle, nerves and ganglia.

The clinical picture of paramyxoviruses (PMV) can include diarrhea and melena. The pathogenicity, types of lesions and clinical signs seen depend on the serotype and strain of the virus and the host's susceptibility. PMV-1, which causes Newcastle Disease, has caused gross hemorrhage (due to vasculitis of the intestinal wall) and necrosis of submucosal lymphoid tissue in the intestines of some birds.⁵⁷

Adenoviruses also cause hemorrhagic enteritis in psittacines, American kestrels and turkeys, and a greenish diarrhea in pigeons and galliforms. ^{57,128} In affected psittacines, gross necrosis and hemorrhage are noted. Histologically, inflammation is variable, thrombosis of

intestinal capillaries is evident, and the enterocytes contain large basophilic intranuclear inclusions.⁵⁷

The intestine is the primary site of infection by various protozoal agents. Coccidia are some of the most widespread and well-known agents, consisting of several genera affecting a wide range of birds. Coccidia's pathogenicity may range from inapparent infections to severe hemorrhagic diarrhea and death. Eimeria is most common in pigeons and galliformes, whereas Isospora is primarily found in psittacines and passerines. 129 Both species have direct life cycles, with transmission occurring via ingestion of sporulated oocysts in fecal-contaminated food or water. 129 Disease is often precipitated by stress. Diagnosis is via detection of large numbers of oocysts in the fecal wet smears or floatation. Antiprotozoal treatments include toltrazuril (7 mg/kg orally every 24 hours), sulfa-based drugs or amprolium. 77,81 Cryptosporidiosis has been diagnosed in over 30 avian species and is considered an uncommon disease of the young and immunosuppressed (Figs 14.16a-c). 130 The only confirmed speciation in a non-galliformes was the detection of Cryptosporidium meleagridis in an Indian ring-neck parrot chick presented with diarrhea and delayed crop emptying.¹³¹ Treatment has been covered previously. Microsporidia, primarily Encephalitozoon bellem, has been diagnosed in lovebirds, budgerigars, Amazon and eclectus parrots¹³² and Gouldian finches. ¹³³ Infection has been linked to concurrent disease, especially circovirus infections, 132 and other causes of immunosuppression.

Flagellated protozoa are also recognized as causes of enteritis. Giardiasis has been diagnosed in a variety of psittacines, poultry, waterfowl, finches and toucans.⁷⁷ Clinical signs vary from inapparent infections to weight loss, failure to thrive, diarrhea⁷⁵ or even feather picking in cockatiels in the USA.¹³⁴ Diagnosis is via direct fresh fecal examination for the presence of the pear-shaped trophozoites, trichrome fecal staining or ELISA testing. Treatments used successfully include ronidazole, metronidazole, dimetridazole and fenbendazole. 75,77,134 Hexamita/ Spironucleus spp. occasionally cause enteric signs of variable pathogenicity in galliforms, pigeons and parrots.77, 134 They can be recognized by their cigar shape and rapid motility and are more difficult to clear than are giardia.134 Cochlosoma spp. cause lethargy and moist bulky droppings, as well as dehydration and death in young Gouldian finches being fostered under Bengalese finches. Adult birds are unaffected, although they may have bulkier stools. The Bengalese finches act as an asymptomatic carrier, as do a range of other finches, but not adult Gouldian finches. 135 The organism is characterized by its six anterior flagella and a helicoidal anterior ventral sucker; it is diagnosed on wet mounts of fresh fecal samples. Transmission is via the fecal-oral oral route, and the

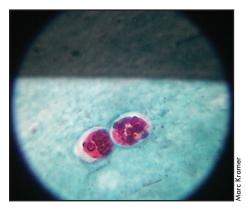

Fig 14.16a | Acid fast stain of a fresh stool specimen showing a form of cryptosporidium.

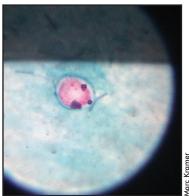

Fig 14.16b | Another form of cryptosporidium from the stool. Acid fast

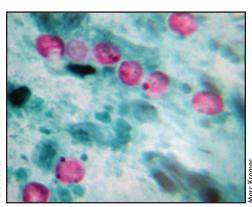

Fig 14.16c | A necropsy specimen had a proventricular scraping acid fast stained. The tissue forms of cryptosporidia are shown.

organism appears to be very sensitive to antiprotozoal drugs such as ronidazole and metronidazole.135

Nematode parasites are commonly diagnosed in Australian psittacines, although other psittacines have also been infected. 129,136 Pigeons, galliforms, waterfowl and toucans are just some of the other species susceptible. Nematodes are particularly a problem in wild-caught birds or those housed in planted aviaries that favor the parasite's life cycle. Ascarids and Capillaria spp. are most commonly diagnosed (Fig 14.17). They cause ill thrift, weight loss, diarrhea and death. Transmission is either direct by ingestion of embryonated eggs or indirect via ingestion of an intermediate host, depending on the parasite species. Diagnosis is via fecal floatation and identification of the offending eggs. Treatments include benzimidazoles, levamisole, ivermectin, moxidectin and pyrantel (4.5 to 25 mg/kg per os repeated in 14 days).81,136 Capillaria spp. can be particularly difficult to eradicate, and high doses of anthelmintics may need to be given. Beware of toxicities associated with high doses. For example, Columbiformes appear susceptible to toxicosis after treatment with fenbendazole or albendazole at 50 to 100 mg/kg.137 Secondary bacterial infections may also need to be addressed, and supportive care such as warmth, fluid therapy, nutritional support and intestinal lubricants and laxatives may all be helpful. Environmental control is paramount. Avoiding contact with contaminated feces and providing a dry environment to stop embryonation of eggs are all important. Decreasing environmental load and reinfection of an aviary by suitable housing and quarantining of new birds are all recommended.

Cestode infections can cause problems in the avian intestinal tract. Since their life cycles are largely indirect and involve an intermediate host such as an insect, mollusk or arthropod, cestodes are more a problem of birds with access to the ground.77,129 They are most common in insectivorous finches and parrots of wild stock, particu-

Fig 14.17 | A lethal intestinal nematode obstruction in this Quaker parakeet is an unusual finding in captive raised pet birds in the USA. To compound the issue, a fecal exam for parasites was negative.

larly cockatoos, African greys and eclectus parrots. 129 Infections may cause diarrhea, ill thrift and death, particularly in finches. 138 Diagnosis is via the presence of proglottids in the feces. These may rupture, releasing the eggs. Microscopically, the eggs contain the hexacanth larvae with six hooks on the oncosphere. In some birds, the cestode can be visible, protruding from the cloaca after defecation. However, proglottids may not always be shed or may not rupture, so infections can be missed. Praziquantel (10 to 30 mg/kg orally, repeated in 14 days)77,81,138 appears to be the most effective cestocide. Avoidance of exposure to intermediate hosts is important in control.

Intussusception

Intussusception of the distal small intestine is less common in birds than in mammals and mostly occurs in gallinaceous birds secondary to enteritis.44 As the proximal segment telescopes into the distal segment, blood flow is impaired and intestinal necrosis follows. Rectal intus-

Fig 14.18a | A malnourished female budgerigar with rhinal discharge over a hyperkeratotic cere.

Fig 14.18b | Same budgerigar in (a) showing swollen abdomen.

Fig 14.18c | The swelling was caused by massive fecal retention. A celomic mass, usually a tumor, is involved in such an obstruction. Changing the angle of the vent allowed 5-10 cc of feces to be removed, temporarily giving the bird and the owner time to decide on the final fate.

Fig 14.18d | An intestinal obstruction resulting from autoobstruction in a parrot due to a necrotic intestinal lining slough. The cause was never determined. The necrotic section passed on day 3 of tube feeding and fluids, and the bird recovered.

susception may result in the rectum telescoping onto itself or into the coprodeum, where it may protrude from the vent lips. Both of these are medical and surgical emergencies, which may involve resection of the offending piece of bowel using magnification, and very fine sutures. (6-0 to 8-0).⁹⁰

lleus

Ileus or intestinal hypomotility/amotility can be caused by both physical obstructions (in the intestinal lumen, wall or as a result of external extra-intestinal compression) and by poor motor function. Examples of the former include foreign bodies, neoplasia, heavy parasite burdens, granulomas, strictures and various torsions and adhesions. Paralytic ileus can be caused by enteritides, PDD, peritonitis, lead toxicity and thrombosis of splanchnic vessels.44 The impaired section of bowel dilates with intestinal fluid and gas. The bird becomes dehydrated. Ischemic necrosis of the intestinal wall leads to further fluid and protein loss. Gram-negative bacteria proliferate and produce endotoxins that can result in shock. Death can occur within 24 to 48 hours. Depending on how acutely the bird is affected, clinical signs can vary from vomiting, diarrhea, depression, listlessness, anorexia, decreased fecal output and emaciation. 44,90 In affected birds, abdominal palpation is resented.37,115 Plain

and contrast radiography may reveal dilated gas-filled bowel loops and identify the location of any obstructions. Supportive therapy with fluids, antibiotics, particularly for anaerobes, and analgesia are all recommended. Corrective surgery may then be performed to either remove or relieve any obstructions or to resect any debilitated sections of bowel.

Neoplasia

Primary intestinal neoplasms include carcinomas, papillomas, smooth muscle tumors and lymphosacoma. ^{57,85} Lymphosarcoma presents as diffuse or nodular thickening that may be mistaken for other conditions such as mycobacteriosis. Leiomyomas and leiomyosarcomas present as firm, red-brown masses within the intestinal wall and can only be distinguished from one another histologically (Figs 14.18a-d).⁵⁷

DISEASES OF THE CLOACA

Infectious

Speculums allow complete observation of the cloaca (Fig 14.19). Internal Papillomatous Disease (IPD) can be responsible for the irregular, cobblestone mucosal lesions seen in the psittacine proctodeum (Figs 14.20). IPD is one of the most common cloacal masses seen in

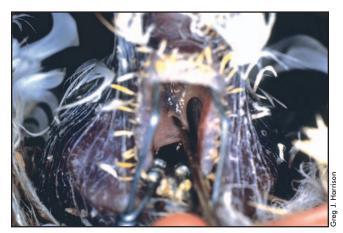

Fig 14.19 | A cloacal speculum can make observation of this complex structure much more understandable. The probe on the left side is in the vagina of a female cockatoo with PBFD. The fold containing the vaginal orifice separates the urodeum from the proctodeum. The bird is in dorsal-ventral position.

Fig 14.20 | Gastrointestinal disorders often involve papillomatosis. Any case of loose or smelly stool in a susceptible species should be investigated.

birds, particularly South American species. Moderate to severe lesions may lead to partial proctodeal obstruction.31 Affected birds typically present with tenesmus, bloody droppings, malodorous feces, flatulence and staining of the vent and tail feathers with urofeces. Definitive diagnosis is via biopsy, but affected lesions will usually blanch when dilute acetic acid is applied to them. Various treatments have been suggested. These include sharp surgical excision, electrosurgery, silver nitrate cautery, cryosurgery, laser surgery and mucosal stripping. 139 All procedures carry the risk of causing iatrogenic traumatic cloacitis. Recurrences of the papillomas are common. Some lesions spontaneously regress but may recur. An empirical report of a commercial pepper diet allowing regression, as long as birds were fed the diet, has been reported (G. Harrison, personal communication, 2000) (see Chapter 32, Implications of Viruses in Clinical Disorders).

Bacterial cloacitis is rare in most birds but can create significant pathology when it occurs. It can occur as a result of localized trauma (such as cloacoliths, chronic cloacal prolapse), coexisting disease (such as internal papillomatous disease) or nutritional deficiencies. Candida spp. have most commonly been isolated from the proctodeum and vent lips but Trichosporon begielli has been found in one immunocompromised macaw.31 These infections should be treated with appropriate antimicrobials both topically and systemically, and any underlying causes need to be corrected.

Cloacoliths are firm aggregations of urates that collect in the cloaca. They will at times also contain fecal material. They are often the result of iatrogenic intervention for other cloacal disease (eg, surgery or during forceful cloacal examination or sampling). The exact pathogenesis of cloacolith formation is unknown but is believed to

involve impaired defecation with retention of urates that may cause dehydration. This may solidify and chemically alter the urate mass, causing it to form a solid structure. Gentle removal, application of topical cleaning, antibiotic and anti-inflammatory agents, systemic antibiotics and regular monitoring of the affected area may be required. In chronic cases, recovery can be slow and characterized by repeated recurrences.

Cloacal Prolapses

Cloacal prolapses are not uncommon in birds and can take one of several forms. Oviductal prolapse occurs in egg-laying females that strain excessively to lay due to uterine or egg-related factors. These often need to be surgically repaired, which may involve a hysterectomy if the oviduct damage is severe. Endoscopy may need to be performed to differentiate oviductal from rectal prolapses. Idiopathic coprodeal prolapse is seen in male cockatoos in particular and less commonly in other psittacines. The exact cause is unknown, but it is suspected that affected birds have never been fully weaned, are bonded to their human companions and interpret their owner's behavior such as petting as sexually stimulating. This is distinct from the overt masturbation exhibited by some cock birds in the presence of the owner. Various surgical techniques have been described, including cloacopexy of the ventral cloaca to the abdominal wall and ventplasty. Hormonal investigations and chemical and surgical neutering are all being evaluated.31 Behavioral modification may be appropriate. A true intestinal prolapse can occur if a rent from the cloaca or rectum is opened into the abdomen (Fig 14.21).

Phallic Prolapses

Phallic prolapses have been described in waterfowl and

Fig 14.21 | A massive intestinal prolapse contains the congested pancreas. This can only occur from a fistula from the cloaca or rectum into the peritoneal cavity.

ostriches and result from excessive sexual stimulation, particularly in younger males, as well as other causes of phallic trauma and underlying systemic disease. 139 Cleaning and replacement of the phallus in the ostrich so that the tip is resting in the dorsal cloacal sulcus and sexual rest are the treatments of choice. Occasionally stay sutures across the vent may be required to keep the phallus in place. Treatment with antibiotics and anti-inflammatories may be necessary if the phallus has been traumatized. 139

Neoplasia

Cloacal carcinomas are infiltrative tumors leading to thickening of the cloacal wall. Smooth muscle cloacal tumors are infrequently reported.⁵⁷

Diseases of the Exocrine Pancreas

Although diseases affecting the pancreas will often impair both endocrine and exocrine function, only the exocrine effects will be discussed here.

Pancreatitis occurs when the digestive enzymes such as trypsin, protease and phospholipase are prematurely activated within the gland and begin to digest it. The resultant damage to the cell wall leads to the release and activation of these enzymes into the ducts and extracellularly. Free radicals are produced causing further damage. The initiating cause of this autodigestion can be difficult to pinpoint, but several factors have been recognized. 140 Viral infections such as Paramyxovirus type 3, herpesvirus, polyomavirus, adenovirus and avian influenza A can cause necrosis and variable inflammation. PMV-3 can also cause chronic pancreatitis leading to a firm and irregular pancreas. Histologically, a variably lymphoplasmocytic inflammation can be seen, with the formation of lymphoid follicles evident. Neophema spp. seem particularly susceptible to this form of the disease.75 A number of bacterial agents have also been associated with pancreatitis. Non-infectious causes include obesity associated with fatty diets or

high fat meals, zinc toxicosis and secondary damage from egg yolk peritonitis. High son all seed diets seem particularly prone to pancreatitis. Psittacines, particularly quaker parakeets, may die suddenly from acute pancreatic necrosis. The pancreas from affected birds appears pale and firm and may exhibit variable degrees of hemorrhage. There is often necrosis of adjacent fat. Histologically, the lesions include coagulation necrosis of pancreatic acini, intralobular hemorrhage and necrotic foci in mesenteric adipose tissue. Zinc toxicity targets the pancreas, causing vacuolation and degeneration of acinar cells. Grossly, the pancreas may appear normal or exhibit mild parenchymal mottling.

Diagnosis of pancreatitis can be difficult. Clinical signs are non-specific but may reflect gastrointestinal dysfunction and pain. Vomiting, diarrhea, anorexia, lethargy, ileus, weight loss, polyuria and polydypsia and abdominal distension are some of the signs noted. 140,141 Signs of abdominal pain include kicking, feather plucking (especially around the abdomen), falling off the perch, widebased stance, sudden flight attempts, aggression and obsessive chewing. Measurement of blood amylase levels has been described, but absolute normal values are yet undetermined for most species. However, amylase levels above 1,100 IU/dl are considered elevated. 140,141 Increases of only 2 to 3 fold may be attributed to extra-pancreatic causes such as gastrointestinal disease (eg, small intestinal obstruction), renal disease or glucocorticoid administration. Thus, interpretation of blood levels needs to be done with care. Pancreatic biopsy is the method of choice for diagnosing pancreatic disease. This can be achieved via laparotomy or endoscopically through the right thoracic air sac. A histological examination may also shed light on likely effective treatments and prognosis.

Treatments for pancreatitis are based on mammalian strategies. Hold therapy to improve pancreatic perfusion is important. Converting birds onto low-fat pelleted diets is preferred to withholding food due to the high metabolic caloric requirements of most birds. Analgesia (eg, butorphanol, carprofen) to counteract abdominal pain, intestinal motility stimulants such as metoclopramide or cisapride to counteract intestinal ileus and parenteral antibiotic therapy are all of value in dealing with this disease. Any underlying causes should also be treated (eg, zinc toxicosis). Some workers have used omega-3 fatty acids for their lipid stabilizing and anti-inflammatory properties. Some workers have used onega-3 fatty acids for their lipid stabilizing and anti-inflammatory properties.

Pancreatic enzyme therapy may help stop pain by inhibiting the endogenous production of pancreatic enzymes; it is useful in treating pancreatic insufficiency,

which may follow a bout of acute pancreatitis. ¹⁴¹ Exocrine pancreatic insufficiency manifests in the production of pale voluminous feces. It can result from any chronic inflammatory process that may affect the pancreas, including those listed as causing acute pancreatitis.

Pancreatic neoplasms can be either benign or malignant. Birds suffering from IPD seem to have a high incidence of pancreatic adenocarcinomas¹⁴² that may present as

masses that have caused adhesions between viscera and peritonitis.⁵⁷

Evaluating and Treating the

Liver

MANFRED HOCHLEITHNER, Dr med vet, Dipl ECAMS; CLAUDIA HOCHLEITHNER, Dr med vet; LORI DANIELLE HARRISON, DVM

Hepatic dysfunction is among the most common medical problems seen in companion birds.^{7,16} In many cases, the involvement of the liver in the overall disease process is not obvious. This chapter reviews the basic pathophysiology, diagnosis, clinical signs and the current therapies for liver disease.

The Role and Function of the Liver

The liver is the largest organ in the body, but its relative size varies among species. The liver performs many critical functions that maintain homeostasis. Liver functions include synthesis of cholesterol and bile acids and the generation and utilization of glycogen. It also is the site for metabolism of various substances in preparation for their excretion from the body via the bile or urine. It is the site of production of plasma proteins, albumin, fibrinogen, lipoproteins and a variety of alpha and beta globulins. The liver produces all clotting factors. The liver filters from the blood infectious agents and foreign materials that have been absorbed by the intestines. This helps prevent these materials from gaining access to the systemic circulation. Energy is produced by oxidative phosphorylation and beta-oxidation of fatty acids in hepatic mitochondria. This energy is used to sustain the activity of the liver and to provide a reservoir of glycogen for the body.

HEPATIC DYSFUNCTION

Hepatic dysfunction occurs after severe injury or repeated significant insults. The liver has considerable functional reserve and regenerative capacity. Only lesions that affect the majority of hepatic parenchyma are likely to produce the signs of hepatic failure. Focal lesions rarely destroy sufficient parenchyma to deplete the liver's

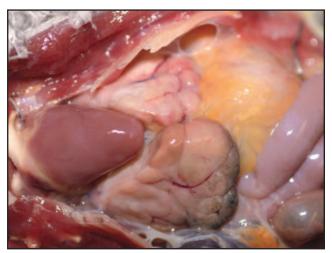

Fig 15.1 | The marked change in color and liver texture are characteristic of cirrhosis.

reserve. The term hepatic failure implies loss of adequate function from either acute or chronic damage, however, usually not all functions are lost at the same time.

METABOLIC DISTURBANCES AS A RESULT OF HEPATOPATHY

Decreased hepatic function can be manifested by a variety of metabolic disturbances. The type and duration of the disorder may influence the nature of the metabolic perturbation. Coagulopathies, hypoalbuminemia, cutaneous manifestations and increased resistance in the blood flow through the liver due to fibrosis are common.

RESPONSE OF THE LIVER

The destruction of hepatic parenchyma results in regeneration, fibrosis and/or biliary hyperplasia. The liver can rapidly and efficiently regenerate lost hepatic mass. Extensive hepatic necrosis is usually followed by parenchymal regeneration without scarring, as long as the normal extra-cellular matrix remains intact. Chronic hepatic injury most commonly manifests as fibrosis. Early fibrosis may respond to treatment or removal of the source of injury, but more advanced fibrosis is generally irreversible with the therapies currently available. Hepatic fibrosis can be produced by a variety of hepatic injuries. The hepatic stellate cells change from the typical lipid-storing cells to cells with a myofibroblastic appearance that subsequently develop the ability to synthesize collagen, leading to hepatic fibrosis. Stellate cells can be activated by various cytokines produced either by inflammatory cells that infiltrate damaged hepatic parenchyma or by constituent cells of the liver (Kupffer cells, endothelial cells, hepatocytes). Damage to the extracellular matrix also stimulates activation of hepatic stellate cells, as do various toxins. End-stage liver disease or cirrhosis as a result of chronic fibrosis is characterized

by loss of normal hepatic architecture due to nodular regeneration of parenchyma, fibrosis and, often, biliary duct hyperplasia (Fig 15.1). Often, clinical manifestations of hepatic failure do not occur until the end stage. The cause of the hepatic damage that leads to end stage liver failure frequently cannot be determined by the time signs of hepatic failure are observed.

Diagnosis and Clinical Signs of Liver Disease

Clinical signs of hepatic failure in birds are variable and can range from mild inappetence and inactivity to acute hemorrhage and death. A large percent of liver tissue must be affected before any obvious clinical signs are observed because of the liver's large functional reserve (Table 15.1).

All birds on a poor diet (seeds, poor-quality formulated diets) should be presumed to have decreased functional hepatic mass (see The Improper Diet Cascade in Chapter 4, Nutritional Considerations: Section II, Nutritional Disorders). The liver's ability to regenerate may mask underlying liver disease in its early stages.

There are some clinical signs that are highly suggestive of hepatic failure, however, none are pathognomonic. Hepatic failure is associated with yellow or green discolorations of the urates and/or the feces, which may result from biliverdinuria or bilirubinuria (Fig 15.2). Feathers develop a glossy black color due to the exposure of melanin from total loss of normal green or blue pigment. Hepatomegaly and/or ascites may cause dyspnea. Weight loss, poor feathering, diarrhea, overgrowth and bruising of the beak and nails, bruising or bleeding of the skin

Table 15.1 | Clinical Signs of Liver Disease

Clinical Sign	Non-specific	More Specific
Anorexia	✓	
Lethargy	✓	
Weight loss	✓	
Weakness	✓	
Diarrhea	✓	
Polyuria	✓	
Polydipsia	✓	
Poor feathers	✓	
Dyspnea	✓	
Green or yellow urates		1
Abdominal swelling		1
Ascites		1
Coagulopathies		1
Melena		1
Abnormal beak/nails		/
Malcolored feathers		1

Fig 15.2 | Yellow urates. See Chapter 23, Diagnostic Value of Biochemistry, for a discussion of biliverdin (green) versus bilirubin (yellow).

and prolonged clotting time may be associated with hepatic failure. Clinical disorders of any type that frequently recur or are resistant to diagnosis and therapy often involve liver malfunction. Diagnostic testing is used to support the diagnosis of liver disease (Table 15.2).

CLINICAL PATHOLOGY

Analytes such as alanine aminotransferase (ALT), lactate dehydrogenase (LDH) and serum alkaline phosphatase (SAP) are not sensitive or specific for liver disorders in birds^{7,11} (see Chapter 23, Diagnostic Value of Biochemistry). Aspartate amino transaminase (AST) is sensitive but not specific for hepatocyte necrosis in birds because AST also is released from damaged muscle tissue. AST levels should be examined in conjunction with creatine phosphokinase (CPK). If only AST is elevated, liver damage is more likely.

Elevations of bile acids are often consistent with hepatic insufficiency and decreased liver function. ¹⁶ Therefore, bile acid assays are useful in determining chronic, long-standing and non-inflammatory states of decreased hepatic function that may not be reflected in hepatic enzyme elevation. Since food (protein) does not affect bile acids in psittacines, pre- and postprandial sampling is unnecessary. Species differences may exist. See Chapter 23, Diagnostic Value of Biochemistry.

An elevated white blood cell count (WBC) is common in bacterial and fungal infections, while a depressed WBC is more common in toxic and viral disorders. Lowered serum total solids, hypoalbuminemia, hyperglobulinemia, and hypokalemia also are indicative of hepatic compromise.

Biliverdin is the most important bile pigment in birds; therefore, icterus is not a typical clinical sign of hepatic

Table 15.2 | Diagnostic Approach to Assess Liver Disease in Birds

History	
Baseline testing	Complete blood count/chemistries/urinalysis
Non-invasive imaging	Radiology and ultrasound
Screening for infectious diseases	See Chapter 21, Preventive Medicine and Screening
Liver function testing	Bile acids
Abdominocentesis	Culture, cytology, chemistries
Coagulation testing	See Chapter 23, Diagnostic Value of Biochemistry
Liver biopsy	Culture, cytology, histopathology

Table 15.3 | Radiographic Findings

Common Radiographic Findings	Interpretation	Comments
Hepatomegaly	Hepatic lipidosis, cardiac-portal hyper- tension, infection (viral, bacterial, fungal)	The liver shadow of neonates can appear bigger because the proventriculus in neonates is relatively larger.
Normal hepatic size	Early stage of hepatopathies	Normal size may indicate normal liver.
Microhepatia	End stage cirrhosis, congenital small liver, emaciation, chronic malnutrition	Species predilection exists: umbrella, Moluccan and palm cockatoos, macaws.

Table 15.4 | Hepatomegaly

Common Causes in Neonates	Common Causes in Adults
Normal neonate	Obesity
Hepatic lipidosis	Hepatic lipidosis
Hepatic hematoma	Bacterial hepatitis: Chlamydophila spp., Mycobacterium spp.
Viral hepatitis	Lymphoma
Lymphoma	Hepatic adenocarcinoma
	Fungal hepatitis
	Viral hepatitis: herpes
	Iron storage disease
	Ovarian disorders

failure. Carotene pigments from the diet may be responsible for yellow skin and plasma color. ¹⁴ A study in broilers with gross hepatic bile duct lesions traced the yellow color of the pericardium and carcass to bilirubin. ¹⁹ In some cases, bacterial reduction may be responsible for the degradation of avian biliverdin to bilirubin. One practitioner has found elevated bilirubin levels in cockatiels with yellow urine, urates and feathers that were normally white, but turning yellow to gold (G. Harrison, personal communication). Other liver function tests are available, but currently their use in the practical setting is limited. These tests include clearance of indocyanine green and bromsulphalein.

RADIOLOGY

Hepatomegaly and microhepatia are common findings in birds. Great variations appear among psittacine species but also between individuals. Baseline radiographs of each individual bird should be taken as a part of the routine examination and may be used for comparison in subsequent years (Tables 15.3, 15.4).

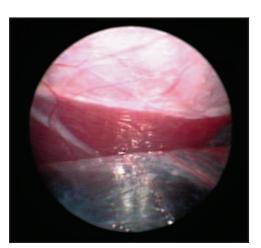

Fig 15.3 | The normal liver with a sharp border and dark brown mahogany color as seen through the membranes of the air sacs.

ULTRASOUND

This test provides information concerning the size and structure of the liver. In most cases, it is not stressful. To prevent hypothermia and ensure good contact of the probe with the bird, warmed lubricating jelly should be used.

ENDOSCOPIC EXAMINATION AND BIOPSY

Liver biopsies are frequently utilized to establish a definitive diagnosis of the pathophysiology of liver disease (Fig 15.3). The risk to the patient in order to gain this information must be considered. Coagulopathies associated with hepatopathies increase the risk of severe bleeding. These authors find very few situations in which liver biopsies are advantageous to the individual avian patient. Many infectious agents responsible for hepatopathy can be diagnosed via serology. Viral infections that are not readily diagnosed via serology are often of short duration. When a diagnosis has been made, treatment for many pathological conditions is purely supportive. Liver biopsy will not change the prognosis in most cases of hepatic dysfunction in parrots. Exceptions would include infection with Mycobacterium spp., various neoplasias and conditions unresponsive to therapy. In an aviary situation, hepatic biopsy or submission of necropsy specimens can be a significant means of identifying and eliminating disease. The risk of loss of an individual may benefit the entire flock and to justify the procedure.

A retrospective study of liver biopsies of 71 birds was performed in a zoological collection. Important diagnostic findings included the identification of iron storage disease in mynahs and toucans; presumptive *Atoxoplasma* hepatitis in mynahs; chronic active hepatitis associated with intestinal coccidial infections; and acid-fast organisms or severe amyloidosis in ducks and geese

suspected of harboring mycobacteria.¹⁷ The information was useful, but the 4.2% death rate would not be acceptable in pet bird practice (see Chapter 24, Diagnostic Value of Endoscopy and Biopsy).

Non-infectious Diseases of the Liver

The liver's function as a primary organ of filtration makes it susceptible to a myriad of environmental toxins and irritants (Table 15.5).

HEMATOMA

Hepatic hematoma may present similarly to or in conjunction with pediatric hepatic lipidosis. Hepatic hematoma often occurs in young birds because they have a prominent abdomen, which provides very little keel protection for the underlying organs. In obese birds, the liver is more friable and extends farther into the unprotected region of the caudal abdomen. The hematoma may be visible through the abdominal skin. The extent of anemia and the bird's physical condition will dictate treatment decisions. Parenteral fluids must be given with care. Homologous blood or plasma transfusions can be beneficial using guidelines as in mammals. The ultimate treatment is husbandry and the appropriate amounts of a proper diet.

HEPATIC LIPIDOSIS

Lipids are normally transported to the liver from the gastrointestinal tract and adipose tissue in the form of chylomicrons and free fatty acids, respectively. Within hepatocytes, free fatty acids are esterified to triglycerides that are complexed with apoproteins to form low-density lipoproteins, which are released into plasma as a readily available energy source. Hepatic lipidosis, or fatty liver, occurs when the rate of triglyceride accumulation within hepatocytes exceeds either their rate of metabolic degradation or their release as lipoproteins. Hepatic lipidosis is not a specific disease entity but can occur as a sequel to a variety of perturbations of normal lipid metabolism. Excessive dietary intake of fat or increased mobilization of triglycerides from adipose tissue subsequent to increased demand, such as in starvation or endocrine abnormalities, may be responsible (see Chapter 4, Nutritional Considerations: Section II, Nutritional Disorders). Abnormal hepatocyte function can lead to an accumulation of triglycerides due to decreased energy for oxidation of fatty acids. Excessive dietary intake of carbohydrates can result in the increased synthesis of fatty acids and excessive triglyceride formation. Hepatotoxins or drugs can impair secretion of lipoprotein from the liver.

Table 15.5 | Causes of Non-infectious Liver Disease

- Congenital
- Traumatic: hematoma
- · Hepatic lipidosis: pediatric versus adult
- Amyloidosis
- · Iron storage disease
- Toxins
- Malnutrition

Decreased apoprotein synthesis can occur subsequent to decreased production and export of lipoprotein from hepatocytes. Deficiencies of the amino acids biotin, choline and methionine have been shown to cause hepatic lipidosis in mammals and some species of birds. More than one defect can occur in any given hepatic disorder. Hepatic lipidosis is most commonly seen in the neonate and the obese, malnourished adult bird. See Chapter 19, Endocrine Considerations.

Hepatic Lipidosis (Pediatric): The liver in neonates is typically larger relative to the total body weight than in adult birds. Baby birds affected with hepatic lipidosis present with a common history of being handfed with a commercial formula to which the owners have added a high-fat supplement. The higher fat content of macaw hand-feeding formulas is also implicated in this syndrome when these formulas are inappropriately used on other species (especially cockatoos). Affected babies are often grossly overweight for their age and exhibit severe respiratory distress. These birds must be handled gently and minimally to avoid exacerbation of the condition. Cool oxygenation is the best first step. The enlarged liver reduces lung and air sac capacity. These neonates usually present when the stress of feeding and breathing at the same time has exceeded their oxygen reserves. General nutritional changes that are required include reducing the quantity of food per feeding, adjusting the fat type and content and adding lactulose to the formula. Oral or parenteral fluid supplementation, when tolerated, should be added to keep the initially hyperthermic bird hydrated and to detoxify the body. When possible, further diagnostic testing should be pursued to check for concurrent infection or other diseases (Table 15.6).

Hepatic Lipidosis (Adult Bird): A second group that is predisposed to hepatic lipidosis is the obese adult bird being fed a high-fat diet, which is common in birds with ovarian disorders and hypercholesterolemia. This syndrome can occur in many species, but seems most common in Amazona spp. Long-standing malnutrition in an obese bird contributes to the cause of this syndrome. Septicemia can occur secondarily. The most common clinical presentation is an anorectic bird with a quiet demeanor, although other signs of hepatic dysfunction

Table 15.6 | Treatment for Pediatric Hepatic Lipidosis

- Cool oxygenation: place the bird in an oxygen chamber at 21° C
- Non-lactated fluids when stable
- Antibiotics that do not require hepatic transformation or elimination if bacterial infection warrants
- · Hand-feed small amounts with increased frequency
- Metabolic aids: lactulose^a, milk thistle^b, policosanol^c

Table 15.7 | Treatment of Adult Hepatic Lipidosis

- Fluid therapy guideline: 60-90 ml/kg of non-lactated fluids every 24 hours
- Nutritional support
- Metabolic aids: lactulose^a, milk thistle^b, policosanol^a, psyllium^a, Ayurvedic herbs,^b SAMe
- · Treatment of secondary infections

may be present. Complete blood count and serum biochemistries help confirm the diagnosis and direct treatment. The serum is often very lipemic in spite of fasting. An elevated WBC is often observed. Serum chemistries may be normal or may demonstrate an increase in levels of bile acids, AST, LDH, cholesterol and triglycerides.

Sick birds' caloric needs are 2 to 3 times normal. Diets too low in fat cannot provide sufficient calories. Start the patient on a 100% carbohydrate diet^d, add metabolic detoxifier^e then slowly convert to a sick bird support formula or a hand-feeding mixture^f with adequate caloric content. Further supportive care includes fluid therapy, metabolic aids (lactulose^a, milk thistle^b, psyllium^g, policosanol^c) and antibiotics if needed (Table 15.7). Improvement of nutritional status is critical for complete recovery and prevention of recurrence (see Chapter 7, Emergency and Critical Care).

AMYLOIDOSIS

Amyloidosis is a term used for various diseases that lead to the deposition of proteins in internal organs. The proteins are composed of beta-pleated sheets of non-branching fibrils. The physical properties of amyloid are responsible for its birefringence and apple green appearance in Congo red-stained sections viewed under polarized light. In primary amyloidosis, amyloid light chain protein is derived from immunoglobulin light chains synthesized by plasma cells in affected tissues. Primary amyloidosis may be localized or systemic.18 In secondary amyloidosis, the most common type seen in veterinary medicine, the liver synthesizes serum amyloid-associated protein, which is the precursor to amyloid-associated fibrils. Secondary amyloidosis occurs as a consequence of prolonged inflammation resulting from chronic infection, tissue destruction, stress or chronic antigenic stimulation.18 The

third type, inherited or familial amyloidosis, has been described only in some mammalian species.

Regardless of the cause, amyloid accumulates in the intercellular spaces and impairs the normal access of plasma to hepatocytes. Amyloid deposits can produce varying degrees of hepatomegaly, and extensive accumulations cause the liver to appear pale. In severe cases, affected birds may have clinical signs of either hepatic dysfunction or failure. While hepatic amyloidosis is usually fatal, a case was described in a falcon with hepatomegaly, ascites, leucocytosis, elevated AST, bile acids and iron levels. Abdominocentesis was performed and a milk thistle derivative was administered for a month. The bird survived for over 3 years. ¹⁸ Resolution of the primary cause is the goal in preventing the progression of this condition.

IRON STORAGE DISEASE

Pathological storage of iron in the liver (iron storage disease) has to be differentiated from hemosiderosis. Hemosiderosis is defined as the excessive accumulation of iron in hepatocytes without the alteration of normal tissue morphology. High-risk species for iron storage disease include ramphastids (toucans), mynah birds, starlings and birds of paradise. High amounts of dietary iron seem to be the main cause, although complete pathogenesis is unknown. Most of the susceptible species live in a naturally iron-poor nutritional environment. The mynah was found to have high intestinal absorption and transfer capacity of iron leading to high retention levels (see Chapter 4, Nutritional Considerations). Dyspnea, hepatomegaly, ascites and sudden death are the most common clinical presentations.

Symptomatic therapy to stabilize the bird's respiratory problems should be followed by long-term therapy based on weekly phlebotomy of 1 to 2% of body weight. Dietary sources of iron such as grapes and raisins should be eliminated, and birds should be maintained on a low-iron (20-50 ppm) formulated diet. Therapy with a chelating agentⁱ, has been described as useful (Table 15.8). Items that enhance iron uptake, such as vitamin C, should be avoided. Iron uptake interference by dietary chemicals such as tannin may provide natural protection from excessive iron absorption.

TOXINS

The liver is the most common site for toxic injuries. The liver receives the major amount of its blood supply from the portal vein, which drains blood from the gastrointestinal tract. Therefore, ingested toxic substances including plants, aflatoxins and bacterial products, as well as metals, minerals, pharmaceuticals and other chemicals absorbed into the portal blood are trans-

ported to the liver. The liver possesses enzymes capable of metabolizing a variety of endogenous and exogenous substances for elimination from the body. This metabolic process may alter some substances such that they become more toxic. Toxin production may result in necrosis of hepatocytes, which may be replaced by fibrotic cells or infiltrated with lipids. This process can be self-perpetuating, even if the inciting agent is no longer present.⁹

Infectious Diseases of the Liver

The pathogenesis, diagnosis and treatment of the individual infectious diseases are beyond the scope of this chapter. See Chapter 28, Implications of Mycobacteria in Clinical Disorders; Chapter 29, Implications of Mycoses in Clinical Disorders; and Chapter 32, Implications of Viruses in Clinical Disorders. The reader is referred to other references for more details on infectious diseases that affect the liver (Table 15.9).

Therapy for Liver Disease

This section reviews anecdotal and research-based therapy for hepatobiliary disease in birds; the mechanism of action, potential indications, efficacy as reported in humans and side effects. The liver can regenerate lost hepatic mass rapidly and efficiently. The therapy for hepatic dysfunction is directed at regeneration. Potentially hepatotoxic drugs should be avoided. High-quality nutrients are the best source of support for the regeneration of liver cells. The specific etiologic agent of liver disease is often undetermined. Clinical objectives for treatment of liver disease can be divided into supportive care and pharmacologic therapy.

SUPPORTIVE CARE

Supportive care for birds with hepatic damage includes reducing stress, fluid therapy, nutritional support and treatment of encephalopathy, ascites, coagulopathies and gastrointestinal ulceration. Proper caging options range from a cool, oxygenated incubator in a low-stress area to the bird's normal cage in its household environment. Lowering perches and padding can protect birds with coagulopathies. If infectious disease is suspected, then quarantine would be warranted.

Fluid therapy will flush toxins and toxic by-products through the metabolic pathways and from cells, organs and blood (see Chapter 7, Emergency and Critical Care). The selection of fluids for replacement therapy may be based on serum biochemistry results and physical exam findings and should be devoid of lactate. The volume to be administered will vary, depending on existing fluid deficits and continuing loss. Administration of colloids may be effective in severe non-responsive hypoalbuminemia, however, clotting times should be monitored. Conspecific plasma or whole blood may be a better option.

Nutritional support with gavage-feeding should be provided three to four times daily for the anorectic patient. Calculate the metabolized energy requirements to determine the volume of food to use (see Chapter 4, Nutritional Considerations). A high-quality balanced formula with appropriate levels of vitamins and minerals and devoid of potential hepatotoxic agents, such as pesticides and preservatives, should be provided.

Hepatic Encephalopathy

The goal of therapy for hepatic encephalopathy is to restore normal neurologic function. In mammalian medicine, this is accomplished by dietary protein restriction, lactulose^a therapy and antimicrobials. Lactulose^a is a synthetic non-absorbable disaccharide commonly used in mammalian medicine for the treatment of elevated blood ammonia levels seen in hepatic encephalopathy. It is fermented in the gut by bacteria into acetic acid and lactic acid, which reduces the pH. The acidification causes ammonia (NH₂) to migrate from the blood into the colon where it is trapped as an ammonium ion (NH₄⁺) and expelled with the feces. These acids also increase osmotic pressure drawing water into the bowel, causing a laxative effect. Lactulose^a has minimal side effects and is therefore considered safe to administer to all birds during gavage-feeding.

Ascites

Removal of a large volume of coelomic fluid can cause severe protein loss. Removal is indicated if the ascites is associated with respiratory embarrassment or anorexia. Diuretics may be useful in controlling fluid retention. Dietary sodium restriction also is recommended, but the efficacy is unknown.

Coagulopathies

Cholestasis can cause impaired production of coagulation factors and antithrombin III as well as vitamin K malabsorption. Normal avian values are not available. Coagulopathies may be observed as petechia, hemorrhage or melena. Blood component therapy may be indicated. Vitamin K_1 can be administered for hemorrhage associated with vitamin K deficiency.

Gastrointestinal Ulceration

The empiric indications for the use of H2 blockers include nausea, inappetence and melena. Famotidine or ranitidine are recommended, since cimetidine and omeprazole are involved in cytochrome P450 inhibition and potential drug interactions in mammals.²³ Sucralfate may enhance healing of ulcers in patients with impaired mucosal blood flow, but this agent may bind and prevent absorption of other drugs.

PHARMACOLOGIC THERAPY

The proper choice of therapy depends on a definitive diagnosis. Technical or financial restrictions often preclude obtaining a definitive diagnosis in avian veterinary medicine. Therapeutic agents used are chosen for their anti-inflammatory, antifibrotic, hepatoprotectant, antimicrobial, diuretic, procoagulant, antacid or bivalent chelating actions. The pharmacologic therapies the authors recommend for hepatic failure in birds have not been validated by controlled studies. The personal experiences of the authors as well as anecdotal reports from colleagues support their use in therapy.

IMMUNOSUPPRESSANTS

The use of glucocorticoids in avian medicine is controversial. They cause immunosuppression by a variety of pathways. Glucocorticoids may exacerbate an underlying infection, increase hepatic lipid deposition, derange adrenal function and may be contraindicated unless a definitive diagnosis is determined (see Stress in Chapter 19, Endocrine Considerations). They are the treatment of choice in humans with autoimmune hepatitis.

Azathioprine is a thiopurine analogue metabolized in the liver to 6-mercaptopurine. Its metabolites inhibit the proliferation of rapidly dividing cells and modify T-lymphocyte function. Azathioprine is indicated when glucocorticoids are not controlling the immune response or are not tolerated by the patient. No data exist on the efficiency of conversion of azathioprine to its active metabolites in

112 Clinical Avian Medicine - Volume I

hepatic insufficiency in birds. Serious side effects include dose-dependent bone marrow suppression, pancreatitis and idiosyncratic hepatotoxicity in mammals.

ANTIFIBROTICS

Colchicine is indicated when there is evidence of fibroplasia or bridging fibrosis. Colchicine helps prevent fibrosis by a variety of inhibitory actions. It also may protect the liver via stabilization of hepatocytes' plasma membranes. Most common side effects are associated with gastrointestinal upset, but in humans a peripheral neuropathy and bone marrow suppression have been reported. Formulations of colchicine containing probenecid can inhibit biliary and renal excretion of many drugs. Elemental zinc and glucocorticoids also have antifibrotic properties, but should be used with caution.

CHELATING AGENTS

Chelating agents are used to chelate bivalent metals such as zinc, lead, copper and sometimes iron. Copper induced liver disease is not a common problem in avian medicine.

HEPATOPROTECTANTS

Hepatoprotectants comprise a varied group of compounds that may protect hepatocytes from injury caused by free radicals, bile salts, drugs, environmental toxins and other insults.

Ursodiol, ursodeoxycholic acid, is a hydrophilic bile acid that competes with other bile acids for absorption in the ileum, and shifts the bile acid profile in favor of less toxic hydrophilic forms. It is suspected to reduce hepatocellular injury and fibrosis, modulate immune response and act indirectly as an antioxidant by preventing bile acid-induced peroxidation. Ursodiol is indicated in mammals for chronic active hepatitis, cholangiohepatitis, and disorders involving cholestasis or elevated bile acids. No efficacy studies have been performed with birds. GI upset has been reported rarely in humans. Ursodiol is contraindicated in bile duct obstruction because it is choleretic.

Vitamin E is a potent antioxidant. Studies indicate that it protects against bile salt-induced oxidant injury in-vitro.²⁹ It is indicated as an empirical therapy for inflammatory hepatopathies. The side effects are minimal unless there is a massive overdose or if it used with selenium (see Chapter 4, Nutritional Considerations).

S-adenosylmethionine (SAMe) is an indirect precursor of

the antioxidant glutathione²⁰ (see Chapter 4, Nutritional Considerations: Section II, Nutritional Disorders). There are no side effects reported in veterinary medicine. Neurological side effects were reported in humans taking tricyclic antidepressants.¹² Early empirical results of SAMe use in birds with elevated cholesterol and fatty disorders are encouraging.

Milk thistle^b (*Silybum marianum*: silymarin) is an extract from the seeds of milk thistle. It is thought to have antioxidant effects via scavenging of reactive oxygen radicals, and to have anti-inflammatory effects via inhibition of 5-lipoxygenase.³ Side effects of GI upset and allergic rashes are rare in humans. It is a nutritional supplement, not a pharmaceutical. See Chapter 10, Integrative Therapies for more information.

Policosanol^c is a blend of compounds isolated from natural plant waxes. It decreases blood triglyceride and reduces low-density lipoprotein cholesterol, inhibits abnormal platelet aggregation, protects against low-density lipoprotein oxidation, suppresses arterial inflammatory factors and increases beneficial high-density lipoprotein cholesterol.

Monitoring Parameters

The best test for monitoring the treatment of liver disease is the test(s) that was used to confirm the diagnosis in the first place. If hepatic lipidosis was diagnosed in an obese Amazon by history and clinical signs, hepatomegaly noted on radiographs and an elevated serum bile acid assay, then repeat radiographs and serum bile acid assay would be indicated. Repeat biopsies would give the most definitive answer, but are not always best for the individual patient.

Note to the Reader

The National Research Council (NRC) has not established standards for nutritional products fed to birds; therefore, claims of nutritional completeness can not legally or ethically be made. Human medical textbooks and those of domestic animals have established normal laboratory values, recommended treatment regimes and nutritional disease states — all based on individuals meeting minimum standards of nutrition. These are not available in avian medicine.

Evaluating and Treating the

Kidneys

M. SCOTT ECHOLS, DVM, Dipl ABVP-Avian

Renal diseases and their various classifications are well documented in the avian literature. The precise pathogenesis of avian renal disease, however, is not nearly as well described as it is in mammals. Renal disease has been shown to be fairly common in avian species. In studied poultry, as much as 29.6% of all disease conditions had abnormal pathology associated with or attributable to renal disorders. 20,214,251 Amyloidosis, urate nephrosis and gout were the most common diseases associated with mortality in a 4-year retrospective study conducted at a waterfowl park in Ontario, Canada. 210 Thirty-seven percent of all avian cases presenting with renal tissue for histopathological examination, included over a 15-month period at the Schubot Exotic Bird Health Center, had one or more histologically identified kidney lesions. 187 Nine of 75 pheasants (Phasianus colchicus) died with nephritis, one or both ureters impacted, and visceral gout in another comprehensive study on avian mortality.186 These case reports and retrospective studies support the conclusion that renal diseases are relatively common and are clinically significant in multiple avian species.

When compared to mammalian counterparts, the avian urogenital system has many structural and functional differences, which have been described previously.^{77,90,118,181,187,227} Differences including gross anatomy, renal portal blood flow and protein waste elimination should be considered when reviewing this chapter, as findings obtained from mammalian studies may not necessarily be applicable to birds. By better understanding the pathophysiology of renal disease, practitioners will be able to better diagnose, clinically evaluate and treat kidney disorders in birds.

Part one of this two-part chapter will combine mammalian and avian literature to help describe the pathogenesis and progression of renal disease. Various forms of specific kidney disorders that have been reported in birds are described. Discussions of treatments will be deferred to the second half of this chapter.

Part two will focus on methods of diagnosis and management of specific avian renal diseases. Many of the diagnostics and treatments discussed are rationalized and based on avian renal anatomy, physiology and an understanding of the pathophysiology behind kidney disease, all of which are covered in the first half of the chapter.

PART 1: Pathophysiology, Pathogenesis and Classification of Avian Renal Disease

ANATOMY

Kidneys

The avian renal system is quite unique among vertebrate kidneys. In-depth discussions of gross and microscopic avian kidney anatomy have been covered elsewhere as referenced, but pertinent features will be discussed here. ^{27,38,39,90,113,141} In general, avian kidneys comprise 1 to 2.6% of body weight compared to an average of 0.5% of body weight in mammals. ⁷⁷ Kidney mass also is relatively larger in those birds with active salt glands. ^{77,110} At least in Pekin ducks (*Anas platyrbynchos*), females have more and larger nephrons and bigger kidneys relative to body mass. ¹⁵ Finally, the left kidney in laying hens tends to be heavier and have a higher rate of renal portal blood flow than the right. ²⁴⁸

Birds have paired kidneys located within a cavity formed by the ventral surface of the synsacrum. The kidneys extend from the caudal edge of the lungs to the caudal synsacrum. The synsacrum and kidneys are surrounded by air. In most birds, the kidney is composed of three divisions: cranial, middle and caudal. Figs 16.1a, b demonstrate basic gross renal anatomy. The middle and caudal renal divisions of most passerines are fused, while the caudal renal divisions are connected across the midline in herons, puffins and penguins. Additional variations in gross renal anatomy can be found in other avian species.

Within each division are numerous renal lobules, each containing a cortex and a cone-shaped medulla (medullary cone). Avian medullary cones have no inner and outer regions as described in most mammalian kidneys. 40

One of the most unique features of avian kidneys is the presence of two types of nephrons, with and without a loop of Henle. The loop of Henle allows for urine concentration and is the primary reason that birds and mammals are the only classes of vertebrates that can consistently produce hyperosmotic urine. In birds, only about 10 to 30% of the nephrons are of the mammalian type. Most avian nephrons are loopless ("reptilian" type) and stay within the cortex. The looped nephrons ("mammalian" type) extend from the cortex into the discrete medullary areas known as medullary cones. Since birds have primarily "reptilian" type nephrons, which produce isoosmotic urine, urine concentration is limited.

Neurovascular System (Including the Renal Portal System)

The vascular system surrounding avian kidneys is quite complex and is one of the main reasons that renal surgery is difficult in birds. Another unique feature of avian kidneys is the presence of an arterial and venous, or dual, afferent blood supply. (See Figs 16.1a-e for anatomy of the gross renal neurovascular system). The arterial afferent blood supply to the kidneys is as follows. The cranial renal division is supplied by the cranial renal arteries, which branch off the aorta. The glomeruli and postglomerular tubular network of the middle and caudal renal divisions are supplied by the middle and caudal renal arteries, which branch off the ischiadic or external iliac arteries. (77,141)

The renal portal system forms the second afferent blood supply, which is venous, to the kidneys.¹⁴¹ The external iliac, ischiadic and caudal mesenteric veins supply blood to the renal portal system.²⁴⁸ A ring is formed on the ventral side of the kidneys by the cranial and caudal portal veins, which branch off the external iliac and common iliac veins.¹⁴¹

The renal portal system works by either directing blood to or shunting it past the kidneys as directed by the renal portal valve. For example, venous blood from the limbs is shunted straight to the caudal vena cava when the renal portal valve, within the common iliac vein, is open. The opposite is true when the renal portal valve is closed, as venous flow from the legs is directed to the afferent venous system of the kidneys. This, of course, means that blood may pass through the kidneys prior to any other organ. Additional shunting either to the caudal mesenteric vein (caudally) or internal vertebral sinus

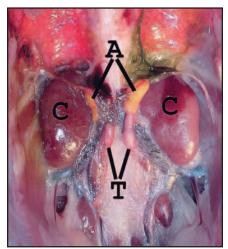

Fig 16.1a | Gross renal anatomy of a normal immature male red-tailed hawk (Buteo jamaicensis) that died from head trauma. Note the testes (T), adrenal glands (A) and cranial renal divisions (C). This hawk has a moderate amount of fat covering the middle and caudal renal divisions.

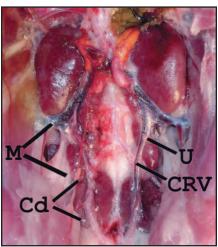

Fig 16.1b | The excess ventral perirenal fat has been removed. The middle (M) and caudal (Cd) renal divisions are now visible. The immature ductus deferens runs alongside the ureter (U) and caudal renal vein (CRV), but is not distinguishable in this young bird.

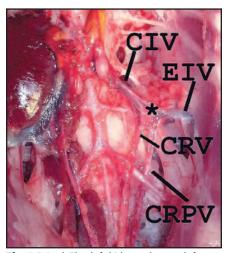

Fig 16.1c | The left kidney, ductus deferens and ureter have been removed, leaving the large vascular structures intact. The external iliac (EIV), caudal renal portal (CRPV), caudal renal (CRV) and common iliac (CIV) veins and the approximate location of the renal portal valve (*) are identified.

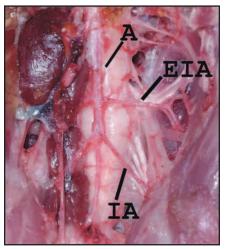

Fig 16.1d | The venous system has been removed to demonstrate the aorta (A), external iliac (EIA) and ischiadic (ischiatic) (IA) arteries.

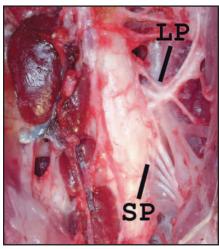

Fig 16.1e | The left renal, vascular, reproductive and endocrine systems have been removed, revealing the overlying renal fossa of the synsacrum and lumbar (LP) and sacral plexi (SP).

(cranially), again bypassing the kidneys, also may occur once blood has entered the renal portal ring.

By route of the afferent caudal and cranial renal portal vein branches, blood is delivered to the peritubular capillary network. He will will will all renal arterioles terminate in the glomerular capillary beds, renal portal blood flow does not. He system allows only arterial blood into the glomeruli and both postglomerular arterial and renal portal vein venous blood to the renal tubules. Blood is ultimately drained out of the kidneys via the centrolobular to the cranial and caudal to the renal and finally common iliac veins just proximal to the renal portal valve. He

This unique system accounts for some clinical concerns. 141 First is the fact that blood can be directed from the lower limbs straight into the renal parenchyma. This may increase the effect of nephrotoxic drugs and/or enhance elimination by taking the compound directly to the kidneys. Some drugs eliminated by tubular secretion and given into the leg may enter the renal portal system and be eliminated without ever entering systemic circulation. 223 As a general rule, parenteral drugs probably should be given in the cranial half of the body. Because some of the venous afferent blood comes from the caudal mesenteric vein (*v. coccygeomesentericae*), which drains the lower intestines, alimentary tract disease may ascend into and have an effect upon the kidneys. As

addressed under Part 1: General Mechanisms and Consequences of Renal Injury, Gastrointestinal Complications, the effect of lower intestinal disease upon the kidneys should be considered and treatment such as antibiotics for colitis instituted.

Hemodynamics

Studied birds have an impressive ability to maintain renal blood flow, even with severe hemodynamic alterations. Chickens seem to be able to "autoregulate" (keep constant) glomerular filtration rate when the arterial blood pressure range is within 60 to 110 mmHg. The Arterial pressures below this "autoregulatory" range result in decreased glomerular filtration rate until urine flow ceases at pressures below 50 mmHg. The Also of interest is that renal perfusion does not decrease in chickens (*Gallus domesticus*) until nearly 50% of the blood volume has been removed. Despite severe hemorrhage, birds are able to maintain their blood pressure, suggesting other compensatory mechanisms such as extravascular fluid mobilization are utilized to ensure normal renal blood flow.

Local Renal Neurologic System

The lumbar and sacral nerve plexi are closely associated with the kidneys. The lumbosacral plexus is formed by the ventral rami of about eight spinal nerves. ¹⁸⁰ From these rami, the first three form the lumbar plexus, which produces the femoral and obturator nerves. In turn, these nerves provide innervation to the stifle extensors and leg adductors. ¹⁸⁰ The lumbar nerve plexus forms dorsal to the cranial renal division and exits the pelvis cranial to the hip joint. ⁵⁹

The sacral plexus is formed by the caudal five to six spinal nerve ventral rami. These nerves go on to supply innervation to the lower leg and some of the proximal leg muscles. The sacral plexus runs through the middle renal division parenchyma and exits the pelvis via the ischiadic foramen. 59,180

Pressure on the nerve plexi can result in non-weight-bearing lameness. ¹⁸⁰ This is the reason why some birds with renal diseases, especially those that cause renomegaly such as cancer, result in one-leg lameness in clinically affected birds. Other causes of one-leg lameness in birds include egg-laying disorders, bumblefoot, testicular cancer and trauma, and should be considered before making a diagnosis of renal disease.

Salt Glands

Salt glands are present in almost all birds, but have important functional significance in waterfowl, marine birds, and some raptors and desert avian species. 15,34,200,213 Birds have limited ability to produce hypertonic urine. As a compensatory mechanism, the extrarenal salt glands

allow birds to adapt to brackish and saline environments and maintain normal electrolyte balance. There is likely an intimate association between renal function and extrarenal NaCl excretion.¹¹⁰

In chickens, the gland appears vestigial, but its anatomical features have been studied. The (supraorbital) salt gland is approximately 2 cm long and 2.5 mm in diameter. The caudal portion is located above the orbit, adjacent to the frontal bone, while the rostral extent is in the lateral wall of the nasal cavity, next to the dorsal and medial turbinates. The salt gland's draining duct crosses under the nasal cavity and opens from the nasal septum, adjacent to the rostral part of the ventral turbinate, into the nasal cavity. Fluid is then removed by shaking movements of the head or by passively dripping from the tip of the beak. Similar features also have been noted in the turkey nasal salt gland.

The salt glands function by providing an extrarenal pathway for the excretion of sodium chloride when the bird must consume salt quantities greater than its relative ability of renal clearance. In some birds, the secreted sodium chloride can reach 10 times plasma concentrations. The salt glands may remove more than 20% of the sodium chloride delivered by blood and have been considered one of the most efficient ion-transporting organs in the animal kingdom. One reference notes that active salt glands can remove 60 to 88% of sodium and chloride eliminated by the bird's body. Salt encrustation may be noted around the nares of dehydrated, heat-stressed birds and represents a gross manifestation of the gland's function.

The gland size depends on the bird's salt consumption, and a hyperplastic response is considered normal in some species. ²¹³ By adding high levels of sodium to the drinking water, salt gland hyperplasia can be induced in aquatic birds, but not in chickens. ²⁰⁰ In general, birds exposed to little salt have small salt glands. Once a bird is exposed to high salt loads, there is a rapid and profound hyperplasia and hypertrophy response that results in a greatly enhanced salt-secretory capacity within 1 to 7 days. ²¹³

Diseases of the salt glands are rarely described. This may imply that salt glands either are infrequently evaluated or are truly uncommonly affected by disease conditions. One study found that domestic ducks induced with plumbism had high concentrations of lead in the salt glands.³⁴ The authors hypothesized that in ducks, salt glands are involved in the elimination of lead. Also, lead toxicity results in obvious renal impairment and possibly damages the salt glands, making it difficult for wild waterfowl to adapt to different saline environments.³⁴ High cadmium intake significantly increased salt gland

mass in Pekin ducks (*Anas platyrbynchos*) and, combined with the toxic renal effects, was believed to adversely affect osmoregulation.¹⁵ Salt gland enlargement from hyperplasia and inflammation are noted incidentally in range-reared tom turkeys.²⁰⁰ Reported clinical signs are mild and consist of localized or unilateral swelling above the eye.²⁰⁰

PHYSIOLOGY

Roles of the Avian Kidney

Undoubtedly, the kidneys play numerous vital roles in birds. One primary role of the kidney is elimination of metabolic wastes. The kidneys also aid the liver in detoxification. He had been save the kidneys are responsible for eliminating numerous metabolites, tissue concentrations of antibiotics (apramycin and ciprofloxacin) and toxins (lead and cadmium) are often highest in renal tissue. As a result, various compounds are best identified and quantified in the kidney tissue.

Renal regulation of water via electrolyte (Na⁺, K⁺, Cl⁻) balance is essential to maintaining intra- and extracellular fluid volumes and osmolalities.²⁴⁸ By regulating fluid volume, the kidneys also regulate blood pressure. Arginine vasotocin is likely the primary mediator in response to dehydration, but norepinephrine, aldosterone, rennin, angiotensin II and prolactin also may each have an effect on avian kidneys and osmoregulation.^{27,88,89,96,131,204,205}

The avian kidney has other endocrine functions and it is likely that future studies will elucidate more roles of this complex organ. One function of the kidney is the production of the active form of vitamin D (1,25- [OH]₂D₃) via the renal enzyme (25[OH]D₃)-1-hydroxylase.^{66,244} Parathyroid hormone also has been shown to have a profound effect on renal excretion patterns of calcium and phosphate in birds. 61,70 As a result, the kidney is partly responsible for mineral metabolism.²⁴⁸ The avian kidney also is the target organ for numerous growth factors, the functions of which are not yet known.⁵⁷ In addition to production in the liver, chick kidneys secrete apolipoproteins and are believed to contribute to the plasma lipoprotein pool.232 This may be a functional response to the lipids coming from the terminal ileum, via the renal portal system, that contributes to production of lipoproteins.232

Fluid Regulation

Fluid regulation in birds is complex, as is true in many other animals. Birds have the ability to absorb and secrete various electrolytes and nutrients, which have some effect on fluid regulation. These osmoregulatory mechanisms are covered in depth in other references. 38,39,90,223,248 As men-

tioned previously, birds have the ability to produce concentrated urine, but because avian nephrons are primarily loopless, urine concentration within the kidney is limited. In birds, the process for concentrating urine is believed to be similar to that in mammals, but in avian species, sodium chloride acts as the major solute, not urea or potassium. The end effect is that sodium chloride does not have as much osmotic force as does urea, further limiting the concentration of avian urine. ²²⁵ Although birds inhabiting arid environments generally produce more concentrated urine than those from the tropics, many exceptions exist. ^{38,39} This leads to other water conservation methods that are variable between species.

In response to dehydration in birds, glomerular filtration and urine flow rate are consistently decreased while solute concentration increases. In studied birds, arginine vasotocin is the natural avian antidiuretic hormone and is believed to be the primary mediator in response to dehydration. Res. 89,204 Increased plasma osmolarity is likely the major stimulus for release of arginine vasotocin. Arginine vasotocin acts by controlling tubular water permeability, and thus the concentrating capacity of the avian kidney. 33

As a component of water and possibly protein conservation, birds have the ability to absorb significant amounts of excreted (renal) water in the colon and ceca.²⁸ This system also allows some birds to regulate electrolyte loss through the urine.²⁴⁸ The ureters empty into the urodeum where reverse peristaltic waves of the cloaca cause a reflux of urine into the cloaca and ceca, which are sites of water reabsorption.^{28,220,236}

The amount of water reabsorbed is highly variable among different avian species. Rock ptarmigan (*Lagopus mutus*) ceca play a minimal role in digestion, but account for 98% of water absorbed in the hindgut.²⁵² In domestic turkeys (*Meleagris gallopavo*), 20 to 40% of the urine is refluxed into the ceca, from which 80% of all fluids that enter are absorbed. It has been shown that 77% of the water, 72% of sodium and 82% of potassium from ureteral urine in Gambel's quail (*Callipepla gambelii*) is subsequently reabsorbed in the ceca, lower intestine, cloaca and rectum.^{28,252} In domestic fowl, it has been estimated that 13 to 28 ml/kg body weight per day of fluid is absorbed in the cloaca.²⁴⁸

Cecectomized birds often have changes in fluid regulation. Cecectomized Gambel's quail and great horned owls (*Bubo virginianus*) temporarily drank more water than controls. Water intake gradually returned to preoperative levels, suggesting a compensatory response either in the intestines or kidneys.²⁵² Cecectomized great horned owls and chickens also have shown a transient increase in water excretion (in the droppings).^{220,252}

While the lower intestines appear to play a significant role in water and possibly electrolyte reabsorption, the ceca apparently do not have an obligatory role in osmoregulation in some species. ²⁵² Additionally, many birds have no functional or anatomic ceca.

No studies were found that demonstrate the effect of lower intestinal disease on osmoregulation. Regardless, diseases such as typhlitis and colitis may adversely affect water and electrolyte balance beyond simple intestinal fluid loss, and should be a consideration when treating affected birds. Aside from nephrotoxic drugs such as aminoglycosides, no studies were found that show a clear correlation between antibiotic use for treatment of colitis/typhlitis and altered osmoregulation.

Uricotelism

Uricotelism is simply the excretion of uric acid as the end product of nitrogen metabolism. Birds lack carbamyl phosphate synthetase, an enzyme needed to synthesize urea from amino acid nitrogen.99 While birds produce very little urea, the avian urea cycle is important, but is primarily related to renal detoxification processes and not nitrogenous waste excretion.248 In birds, xanthine dehydrogenase is the terminal enzyme of purine metabolism and ultimately produces uric acid as the end product of nitrogen metabolism. 106,132 This is an adaptation that allows birds to minimize urinary water loss. Because uric acid is osmotically inactive, little water is required to excrete this nitrogenous waste.248 The true advantage of water conservation in adult birds is debatable, though. The real advantage of uricotelism may simply be the storage of nitrogenous waste in eggs where a water-soluble product such as urea may prove toxic to the developing embryo.248

GENERAL MECHANISMS AND CONSEQUENCES OF RENAL INJURY

Initiation of Renal Disease

Proposed mechanisms of the process of initiation of renal injury and perpetuation of disease are complex, but have been described in mammals. These "mammalian" mechanisms may or may not apply directly to birds, but help form the basis on which some treatments are considered (see Part 2: Treatment, Nutritional Supplementation and Non-steroidal Anti-inflammatories). For this reason, some of the inflammatory cascade that occurs with renal disease is described.

The products resulting from the arachidonic acid cascade have effects throughout the body. For the purposes of this discussion, the cyclo-oxygenase pathway of the arachidonic acid cascade will be briefly covered.

In studied species, the renal medulla and papilla are a rich source of the group of enzymes collectively called prostaglandin synthetases. 62 The action of the prostaglandin synthetase cyclo-oxygenase upon arachidonic acid results in the formation of numerous prostaglandins (PE₂, PGF_{2a} and PGD₂) and thromboxanes (thromboxane A₂ [TXA] and thromboxane B₂), all of which have varying actions on cells. In response to renal ischemia and vasoconstriction, prostaglandin and thromboxane production is altered (primarily increased). These "alterations" subsequently result in varying effects on the body and kidney including changes in renal vascular resistance, blood flow, recruitment of inflammatory cells and other physiologic effects. Non-steroidal anti-inflammatories act to inhibit prostaglandin synthetase and represent another method by which to "alter" these arachidonic acid byproducts and their subsequent actions.62

Specifically, TXA production, secondary to toxic or ischemic injury, is considered the main cause of renal vasoconstriction associated with acute renal failure and is believed to play a pathogenic role in many forms of kidney disease. Thromboxane A₂, again an eicosanoid derived from the action of cyclooxygenase on arachidonic acid, is produced by many mammalian cells including glomerular epithelial and mesangial cells, renal medulla tubular cells and especially platelets. Plate 1

In mammals, TXA causes mesangial cell contraction and is a potent vasoconstrictor. Both of these actions can result in decreased glomerular filtration rate (GFR). 31.91.94.95 Renal vasoconstriction decreases GFR and delivery of oxygen and nutrients to tubular cells, resulting in renal damage. 95 Thromboxane A2 also promotes platelet aggregation and may be partially responsible for hemostatic abnormalities noted with renal disease. 91,190 As histologic progression of renal disease continues when TXA is inhibited, it is possible that TXA only helps initiate kidney pathology. 93

The above-described outcomes of increased TXA production serve only to show some of the possible negative effects of one by-product created as a result of renal injury. Management of these negative effects may be needed, especially when a clearly identified cause such as bacteria in the kidney parenchyma is not found. This then brings up the reasoning behind using products such as omega-3 fatty acids and low-dose NSAIDs (non-steroidal anti-inflammatory drugs) when managing some forms of renal disease.

Brief Review of Selected Potential Consequences of Renal Disease

Kidneys are dynamic organs and are directly or indirectly associated with multiple body systems. As a result,

renal disorders can lead to or be caused from multiple other disease processes. Some processes, such as hypertension, hypercoagulability and the nephrotic syndrome, are well described in mammalian renal disease, but are never or rarely discussed in the avian literature.

Hemostatic Abnormalities

Abnormalities of hemostasis are noted with some forms of renal disease and may lead to additional kidney or systemic disease. Platelet aggregation and activation occur secondary to complement activated antigenantibody interactions and renal endothelial damage. 23,86,91,94 Activated platelets may then release vasoactive and inflammatory products (including TXA), growth stimulation factors and facilitate the coagulation cascade. 91,94 These reactions can result in glomerular damage via glomerular basement membrane thickening and, potentially, hyalinization and sclerosis.94

Fibrinous renal vessel thrombi have been noted in redfaced lovebirds (Agapornis pullarius) with membranous glomerulopathy and in chickens with Erysipelothrix rhusiopathiae sepsis. However, thrombus formation has been suggested to be rare in birds compared with mammals.86,212 Using multiple staining methods, it could not be confirmed that fibrin-like thrombi noted histologically in various psittacine birds with polyomavirus-associated glomerulopathy were truly composed of fibrin. 189

Gastrointestinal Complications

Gastrointestinal ulcerations are reported in some animals with uremia and advanced renal disease, but are rarely mentioned concurrently in clinical reports of birds with kidney disorders.26 In chickens, gizzard erosions have been associated with naturally occurring urolithiasis. 148 Due to the overall lack of reports in the reviewed literature, it is unlikely that birds with renal disease develop gastrointestinal ulcers.

Intestinal inflammation may lead to renal disease. In humans, inflammatory bowel disease (IBD) can be related to renal disorders. 183 In humans, those with IBD have a 10 to 100 times greater risk of developing nephrolithiasis compared with other hospitalized patients. 183 Human IBD patients also may have an increased risk of glomerulonephritis and tubulointerstitial nephritis. 183 The avian coccygeomesenteric vein drains the mesentery of the hindgut into the hepatic portal and/or the renal portal vein.226 Colitis may serve as a source of infectious agents, toxins and inflammatory products to the avian kidney if blood flow draining the colon is diverted into the renal vasculature. As a result, antibiotic therapy should be considered in all cases of colitis, especially when renal disease is suspected or confirmed.

Abnormal Lipid Metabolism

Aberrant lipid metabolism as evidenced by increased serum total cholesterol, low-density lipoproteins and triglycerides has been noted in humans, cats and dogs with renal disease. 31,179 In rats, lipid accumulation is known to stimulate glomerular mesangial cell and excess matrix production known as glomerulosclerosis.31 Hyperlipidemia has been associated with glomerulosclerosis and/or loss of renal function in rats, guinea pigs, rabbits and dogs. 190 Glomerulosclerosis is histologically similar to atherosclerosis and may share a common pathogenesis. 190 Although scarcely noted in the avian literature, abnormal lipid intake, production and/or metabolism may be associated with renal disease in birds, as described below.

High-cholesterol diets actually may induce renal disease in birds. Pigeons supplemented with dietary cholesterol (0.2%, 0.4% and 0.5% of the diet) had a high incidence of end-stage renal disease, atherosclerosis and increased mortality rate compared with controls. 121 Although specific data was not presented, pigeon mortality was influenced largely by the degree and duration of hypercholesterolemia.121 The implication herein is that diets high in cholesterol may lead to renal disease, at least in pigeons.

Gout

Renal disease may lead to numerous other conditions including gout, which can further damage the kidneys or additional body systems.214 Gout reportedly may be caused by reduced excretion of urates or by increased dietary protein (although this has been disputed as discussed under Part 2: Treatment, Dietary Modification). 236 Dehydration and many forms of renal disease including obstructed ureters and general kidney damage can result in decreased uric acid elimination. As blood levels of uric acid rise and exceed the solubility of sodium urate in plasma (hyperuricemia), monosodium urate crystal precipitation is initiated.²³⁶ It has been concluded that gout may not prove to be a nutritional disease in birds except under unusual circumstances such as deficiency of vitamin A.207

Visceral gout results secondarily from elevated plasma uric acid levels and its resultant deposition on visceral organs9 (Fig 16.2). During visceral gout, urate depositions are commonly found on the pericardium, liver and spleen. 134 Additionally, uric acid deposits are noted histologically within the lamina propria of the proventriculus, ventriculus and sometimes intestine and within the kidney, but can be found on or in any tissue. Visceral gout may appear as a white coating when on the capsular surface of affected tissue. Visceral gout has been associated with multiple forms of renal pathology.^{9,214} Experimentally, visceral gout has been induced in chickens fed excessive

Fig 16.2 | An adult cockatiel (Nymphicus hollandicus) with visceral gout. Note the whitish deposits encasing the heart. The bird died with renal failure due to chronic renal fibrosis and interstitial nephritis.

Fig 16.3 | An adult budgerigar (Melopsittacus undulatus) with articular gout secondary to renal carcinoma. The postmortem picture shows subcutaneous "gouty" deposits over the dorsal tarsometatarsus and ventral phalanges. The skin has been teased open with a needle.

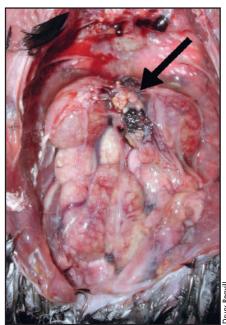

Fig 16.4 | An adult female black lory (Chalcopsitta atra) with severe renomegaly and visceral and articular gout. This female recently laid two eggs, but the ovary (arrow) was quiescent at the time of death. Histologically, renal tubular necrosis with urate stasis and multiple acute "gout tophi" were noted. The etiology was not defined.

dietary calcium and a diet deficient in vitamin A, administered various nephrotoxic agents, and following ureteral ligation and urolithiasis.9,214

Articular gout results from the accumulation of urates in the synovial capsules and tendon sheaths of the joints9 (Fig 16.3). Diffuse urate deposits on visceral surfaces do not occur in articular gout.214 However, visceral and articular gout can be present in the same bird (Fig 16.4). Gross lesions typically consist of soft swellings on the feet at the metatarsophalangeal and interphalangeal joints.²¹⁴ These swellings appear to be painful, as noted in clinical cases. Spontaneous articular gout in birds without underlying renal pathology is relatively uncommon and appears to have a hereditary basis, at least in chickens.214

Continuing Damage

Once renal damage occurs, persistent and progressive kidney damage is likely to occur, even if the initial insult is treated and "cured." In humans, 50 to 60% of children with pyelonephritis develop irreversible lesions of the renal parenchyma.¹³ Although no refereed literature describes the post-treatment progression of renal lesions in living avian patients, the author reported repeated kidney biopsies in numerous birds in an effort to help evaluate their clinical progression.⁶⁴ Repeat biopsies have shown that in birds with histologic confirmation of various kidney diseases, some mild renal lesions persist,

even if the patient is clinically normal or improved.64 When repeating kidney biopsies, the author has noticed no increase in scarring (gross or histologic lesions) or other abnormalities at the prior surgery sites, suggesting some treated birds have good regenerative and/or healing properties. Although these repeat biopsies are encouraging, the long-term health of these patients' kidneys is still unknown.

GENERAL RENAL DISEASE CATEGORIES

Nephritis

Nephritis is simply inflammation of the kidney and may involve the interstitium, tubules and/or the glomerulus (although "glomerulonephritis" is typically reserved for glomerular lesions). While "pyelonephritis" has been described in birds, this term is technically incorrect, as avian species lack a renal pelvis. 116,214 Nephritis is a nonspecific description, but some histological patterns and (especially) identification of infectious organisms help define the etiology.

Glomerulopathies

In the literature reviewed for this chapter, glomerular disease has been loosely termed "glomerulonephritis," but unless inflammation is specifically present, the term "glomerulopathy" would be more appropriate. Glomerulonephritis describes inflammation of the glomerulus, usually considered mediated by the deposition of immune complexes or antiglomerular basement membrane antibodies.^{22,94,239} A more accurate description of glomerular lesions, based on light and electron microscopy and immunohistochemistry, helps define the actual type of glomerulopathy present.

Glomerular disease is the most important cause of endstage renal disease in humans worldwide and of chronic renal insufficiency/failure in dogs. 109,237,239 Proteinuria is the hallmark sign of glomerulonephritis in mammals prior to the onset of clinical renal insufficiency. 94 However, chicken leukocytes lack proteolytic enzymes that would potentially damage the glomerular basement membrane (and allow protein leakage) and birds may, in fact, not develop pathologic proteinuria with glomerulopathies. 22 In one study, no pathologic proteinuria was found in chickens with experimental autoimmune glomerulonephritis. 21 As noted below, glomerulopathies are well documented in avian species, but numerous differences exist when comparing this disease in birds and mammals.

The cause of glomerulopathies is generally assumed to be immune-mediated, but the inciting etiology is often unknown. Membranous nephropathy, the most common cause of nephrotic syndrome in humans, is usually idiopathic and specific etiologies are identified in only 20% of cases. 196 With few exceptions, the causes of glomerulopathies in birds are poorly studied. Polyomavirus infection is associated with membranous glomerulopathy in psittacines.86,189 Glomerular pathology has been noted in chickens with various septic conditions and naturally occurring multicentric histiocytosis. 102,219 Glomerulopathies also can be induced experimentally in chickens by intravenous fungal injections, Plasmodium gallinaceum infections and by feeding aflatoxin. 158,214 Grossly normal 6- to 7-week-old broiler chickens at slaughter have been diagnosed with proliferative glomerulonephritis of unknown etiology. 193 Proliferative glomerulopathy can be induced in pigeons fed diets high in cholesterol.121 It has been suggested that because of the extensive (dual) renal blood supply, severe chronic glomerulonephritis may persist without any clinical manifestation in birds.214 It has been further suggested that avian glomerulonephritis may be present in far more birds than it is currently diagnosed.214

Although humorally mediated immunity is frequently discussed as the etiology of glomerulopathies, research has strongly suggested that cell-mediated immunity plays an important role in producing glomerular disease in chickens and other animals. ^{22,109,237} Under experimental conditions, cyclophosphamide bursectomized (humorally defi-

cient) chickens develop glomerulonephritis. Although gross histologic lesions are similar, bursectomized chickens develop no IgG glomerular basement membrane deposits compared to controls when glomerulonephritis is induced in both groups.²² These and other findings support the conclusion that cell-mediated immunity or some other non-humoral immune response is responsible for inducing glomerulonephritis in chickens. 22,237 Interestingly, in the above described study, even birds with massive mesangial enlargement maintained normal glomerular filtration.22 Due to the small centrally oriented avian glomerular mesangium, the capillary loops were only slightly displaced to the periphery without compromising function.22 Given our current knowledge regarding the differences between avian and mammalian species, renal biopsy is the best way to definitively diagnose glomerular (and other) kidney diseases in birds (see Part 2: Diagnostic Tests, Biopsy).

Infectious Diseases

Bacterial

Certain patterns may be expected with bacterial nephritis. Chickens experimentally infected with *E. coli* (*E. coli* $0_1K_{67}[B_{12}]$), *Staphylococcus aureus* and *Actinomyces pyogenes* developed a fairly consistent pattern and progression of renal disease.²¹⁹

Birds inoculated subcutaneously developed more severe renal lesions and these lesions were noted earlier than those exposed to bacteria per os. Additionally, lesions were more severe in birds infected with E. coli and S. aureus compared to the slight reaction induced from A. pyogenes. Gross renal changes included congestion, enlargement and hemorrhagic foci. Although specific timelines were not given in regard to lesion development, bird kidneys were histologically examined at 4, 7, 10, 14 and 21 days postinoculation. The early-stage lesions consisted of acute interstitial nephritis (mainly lymphocytes, plasma cells and macrophages), prominent congestion and hemorrhage. The lesions progressed to nephrotoxic nephritis and included tubular epithelial cell degeneration and necrosis with the formation of hyaline casts and eosinophilic material. Later histology showed decreased congestion, persistence of mononuclear cells, introduction of connective tissue running around hyperplastic tubules and glomerular lesions.219

Certain renal histologic characteristics, with or without organisms present, may suggest an ascending or hematogenous bacterial infection in the avian kidney. The typical lesions suggestive of bacterial nephritis include tubular dilatation and impaction with inflammatory cells.²¹⁴ As nephritis becomes chronic, tubular necrosis, cyst formation, distortion and interstitial fibrosis with mononuclear cell infiltration become evident.²¹⁴

Using sterile collection and culture methods, bacterial nephritis is definitively diagnosed by recovering bacterial organisms from affected kidneys. Light microscopic identification of bacteria within renal tissue may be difficult, as has been noted in dogs and swine with renal disease. 26,54 In a *Coturnix* quail processing plant outbreak, Erysipelothrix rhusiopathiae was cultured from multiple organs.169 While the kidneys were swollen and congested, no organisms were specifically noted histologically, which emphasizes the importance of tissue culture. 169 Specifically, Escherichia coli has been identified in chickens as a cause of bacterial nephritis (pyelonephritis). 116 As a component of systemic paratyphus, Salmonella typhimurium var. Copenhagen was identified in kidney tissue and most frequently caused interstitial nephritis in a study of 78 experimentally infected pigeons.87 The same organism also was recovered from kidney tissue, as a component of systemic salmonellosis, in pigeons from a large production colony.¹²¹ As is likely true of most viral and fungal renal diseases, bacterial nephritis is often a component of systemic infection and multiple organs may be involved. 187 In summary, any septicemia can potentially result in kidney infection and inflammation (Fig 16.5).

Viral

Viruses perhaps have the most varied effect on avian kid-

neys. Numerous viruses may infect and affect avian kidneys (Table 16.1). Histologic patterns are highly variable, as some viruses, such as pheasant coronavirus-associated nephritis, directly affect the kidneys while others, like psittacine herpesvirus and polyomavirus, damage renal tissue as part of a more systemic process. 126,186,202

Other viruses may cause minimal to no renal disease, but can be identified in the avian kidney because of viremia and/or viral replication and transmission through the urinary tract. For example, the reovirus that causes viral arthritis of chickens infects the kidneys within a few days of inoculation, but causes minimal, if any, renal lesions.¹⁷⁴ Some viral infections such as the West Nile virus are best identified in the kidney, and provide an additional reason to save extra renal tissue (frozen and/or formalinized) for later testing¹²⁴ (Fig 16.6).

Parasitic

Renal Coccidia

Primary and secondary renal parasites have been noted throughout the avian literature and some contribute to significant morbidity and mortality^{18,19,43,69,76,82,83,133,160,175,177,194,217,218,236,253} (Table 16.2). Renal coccidiosis, found predominately in some waterfowl and marine species, is the most frequently reported avian renal parasite in those

Table 16.1 | Viruses Known to Infect or Affect Avian Kidneys

Virus	Common Name	Renal Lesions	Reference(s)
Adenovirus	New gosling virus enteritis virus	Renal hemorrhage	44
	Hydropericardium syndrome in broiler chickens	Renal hemorrhage, tubular nephrosis	2
Astrovirus	Duck astrovirus (aka duck hepatitis II)	Swollen congested kidneys	202
Coronavirus	Infectious bronchitis virus	Interstitial nephritis, urolithiasis, visceral gout and renomegaly	202, 231, 243
Enterovirus	Avian nephritis virus	Renal disease of young chickens and turkeys	202
Herpesvirus	pesvirus Marek's disease Renal lymphoma, renal masses		202
	Psittacine herpesvirus	Renomegaly	202
	Pigeon herpesvirus-1	Renal necrosis	202
Orthovirus	Influenza A of ratites	Renomegaly and green urate-filled ureters	202
Paramyxovirus	Pigeon paramyxovirus-1	Renomegaly, lymphoplasmacytic nephritis	202
Polyomavirus	Hemorrhagic nephritis enteritis of geese	Nephritis	101
	Avian polyomavirus	Basophilic and amphophilic mesangial cell intranuclear inclusion bodies, minimal lesions	126
	Psittacine polyomavirus	Membranous glomerulopathy	202
	Passeriforme polyomavirus	Renomegaly and perirenal hemorrhage	202
Reovirus	Viral arthritis or tenosynovitis of chickens	None to minimal inflammation	174
Retrovirus	Avian Leukosis/lymphoid leukosis	Cancer-nephroblastomas, renal lymphoma/ adenoma/carcinoma, leukemia	202
	Reticuloendotheliosis virus	Renal tumors	202
Togavirus	West Nile virus	Neptritis (Fig 16.6)	124
	Avian viral serositis (EEE)	Pale kidneys	202
	Chukar alphavirus (EEE and WEE)	Urate-distended kidneys	202
	Turkey alphavirus (EEE)	Renal necrosis	202
	Guinea fowl alphavirus (EEE)	Renomegaly	202
	Crane alphavirus (EEE)	Necrotic nephritis and visceral gout	202
	Emu WEE	Renomegaly, necrotic nephritis	202

This table should serve only as an example of the large variety of viruses known to be associated with the avian kidney. EEE = eastern equine encephalitis WEE = western equine encephalitis

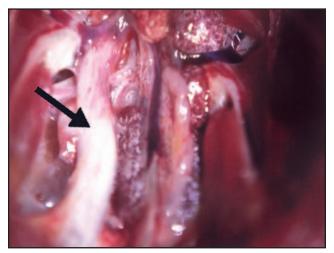

Fig 16.5 | A cloacal carcinoma, right ureteral obstruction (arrow) and Streptococcus sp. nephritis in an adult female Amazona sp. parrot. The Streptococcus sp. isolated from the kidney and heart blood was resistant to enrofloxacin, with which this bird was being treated chronically for cloacal straining.

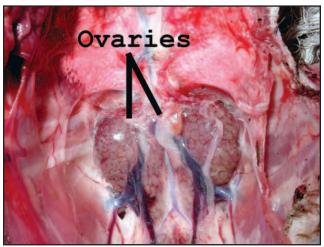

Fig 16.6 | West Nile virus-associated nephritis in an immature female Swainson's hawk (Buteo swainsoni). Note the moderate deposition of fat indicating the bird was in good overall body condition prior to acute death. The kidneys are pale. Two ovaries also are present as indicated by the lines.

Table 16.2 | Reported Incidence of Renal Coccidia in Various Avian Species

Affected Avian Species	Eimeria Species	Associated with Morbidity/Mortality	Reference(s)
Bufflehead (Bucephala albeola)	Unidentified	N/A	84
Canvasback (Aythya valisineria)	Unidentified	N/A	84

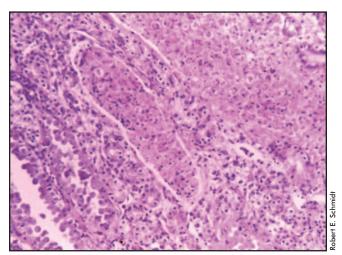

Fig 16.7a | Renal coccidiosis in a screamer (*Chauna* sp.). Note the numerous oocysts and various developing stages of the parasite throughout the renal tubules.

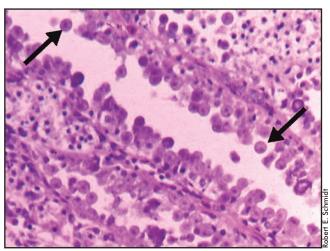

Fig 16.7b | Close up of a renal tubule with numerous oocysts being released into the lumen (arrows).

species and has been clearly associated with disease in some cases. ^{76,82-84,153,160,176,177,217,253} Reports of various other parasitic diseases affecting the kidneys are noted, but their significance is not well established.

Several renal coccidia species have been identified and primarily include *Eimeria truncata*, *E. somateriae*, *E. christianseni*, *E. boschadis*, *E. gaviae*, *E. fraterculae*, *E. goelandi* and *E. wobeseri*. 82,83,133,160 Disease has ranged from mild histologic changes found incidentally (most species) to acute renal failure and death, such as in juvenile eiders (*Somateria mollissima*) and domestic geese (*Anser domestica*). 76,83,217 Flock mortality in domestic geese due to *E. truncata* has been reported to be as high as 87%. 76

Renal *Eimeria* spp. oocysts are passed in feces via the ureter and sporulate rapidly in the environment.²¹⁷ Affected birds typically breed in large colonies or are otherwise under crowded conditions, which likely favors transmission of this parasite.^{177,217} The prepatent period appears to range between species and has included 5 to 21 days.⁸³ Although transmission between different avian species is not clear, one study suggested that renal coccidia of geese do not infect ducks.⁸³

The clinical gross and histologic abnormalities noted with renal coccidiosis seem to be fairly consistent across affected species. Most clinically affected species are young birds. ^{177,217} Clinically affected birds are typically emaciated and may have diarrhea with or without blood. ^{83,160,177,217} It should be kept in mind that many reported birds are wild and also have had intestinal parasites that may contribute to the described clinical signs. Grossly, the kidneys are often enlarged with white to yellowish nodules containing urates and/or oocysts. ^{76,83,160,217}

Cytologic smears of renal tissue and ureters often

contain different endogenous stages of coccidian oocysts. ^{160,177,217} The renal tubules are parasitized and histologic lesions vary from mild dilatation to severe tubular destruction with associated degrees of inflammatory cell infiltrate (unusually mononuclear). ^{76,83,160,177,217} The tubules are often distended with endogenous developmental stages (micro- and macrogamonts, macrogametes) and maturing *Eimeria* spp. oocysts²¹⁷ (Figs 16.7a,b). In severe cases tubular nephrosis, necrosis and interstitial nephritis, potentially causing significant renal dysfunction, may be noted. ²¹⁷

Sarcocystis

Numerous other parasites have been noted in the kidneys of birds, but oftentimes association with disease is not clear. Canaries (*Serinus canaria*) experimentally infected with *Sarcocystis falcatula* developed mild multifocal interstitial renal infiltrates and glomerular hypertrophy with mesangial hyperplasia that modestly progressed with duration of infection.²¹⁸ While precystic merogony was primarily noted in the pulmonary tissue, infected canaries had low levels of merogony in the kidney and other tissues. Similarly infected pigeons developed no renal lesions.²¹⁸ Sarcocystis organisms also have been noted histologically in the renal parenchyma of cockatiels, but again the significance is unclear (T. Lightfoot, personal communication, 2003).

Microsporidia

Microsporidia (*Encephalitozoon* spp.) have been reported in numerous avian species with variable effects on the kidney. A psittacine beak and feather virus-positive eclectus parrot (*Eclectus roratus*) had heavily parasitized (*Encephalitozoon bellem*) kidney cells with associated renal tubular distension. As has been noted in other reported cases, renal cellular reaction was minimal

in the eclectus. Similar histological lesions and parasite morphology and locations (liver, kidney, intestines) also have been reported in three species of lovebirds, budgerigars (Melopsittacus undulatus) and a doubleyellow headed Amazon parrot (Amazona ochrocephala). 175,192,194 The author also has seen renal microsporidiosis in a canary (Serinus canaria) that presented for acute illness and died shortly thereafter. Histology confirmed that numerous microsporidial organisms (not further defined) were present in the renal tubules and were associated with tubular necrosis. Other histologic lesions were minimal to mild, placing renal failure as the likely cause of death. Although it is not clear what role the kidney plays in disease, some believe that E. bellem is an avian and human pathogen, and may be primarily found in immunocompromised individuals. 194

Cryptosporidia

Urinary tract cryptosporidiosis also has been noted in multiple bird species with varying associated disease. Although renal cryptosporidiosis is infrequently reported, it has been directly associated with kidney lesions in a 4-month-old black-throated finch (*Poephila cincta*), an 8-week-old Sonnerat's junglefowl (*Gallus sonneratii*), 4-month-old pullets and adult laying hens. 19,85,170,199,236 Four-day-old chickens co-infected with Marek's disease virus also have been studied. 1 Clinical signs ranged from acute death (finch and junglefowl) to thinning, depression, leg weakness and respiratory distress (4-month-old pullets and 4-day-old chicks) to slightly increased morbidity and mortality (adult chickens). 1,19,85,170,199,236 Pulmonary cryptosporidiosis also was a common feature of the pullets. 170

Similarities were noted among gross and microscopic findings. The affected black-throated finch and Sonnerat's junglefowl had pale and swollen kidneys, and all birds had some degree of tubular epithelial tissue change with organism colonization. ^{1,19,85,170,199,236} The finch, adult layers, pullets and chicks also had interstitial nephritis, while the junglefowl had no inflammatory response. ^{1,19,85,170,199,236} Although no organisms were specifically found in the kidneys, a diamond firetail finch (*Stagnopleura bella*) with proventricular cryptosporidiosis also had similar tubular lesions in addition to multifocal amyloidosis (kidney included), severe chronic urate nephrosis, and protein and cellular tubular casts. ¹⁹

Increased incidence of visceral gout, 1 to 2% higher than expected mortality, and numerous stages of *Cryptosporidium* sp. organisms within the epithelial cells lining the renal collecting tubules and ureters (of histologically evaluated kidneys) were found in egg-laying chickens from a production facility. Visceral gout was likely caused by the partial ureteral obstruction resulting from heavy

diffuse lymphoplasmacytic infiltration in the wall of the ureter and (parasitized) epithelial wall hyperplasia. ²³⁶ Regarding the experimentally infected chicks, the authors concluded that *Cryptosporidium baileyi* can be highly pathogenic, and induce mortality and urinary tract infections in chickens infected with Marek's disease virus (an immunosuppressive effect). ¹ Several authors have hypothesized that urinary tract *Cryptosporidium* infection originates in the cloaca and retrogrades into the kidneys via the ureters. ^{170,236} Although relatively uncommon, urinary tract cryptosporidiosis and associated disease seem to be primarily a concern in chickens, especially those with concurrent immunosuppressive illness.

Flukes

Scattered reports of renal flukes are noted in the literature. Spindle-shaped eggs, belonging to the blood fluke Dendritobilbarzia anatinarum, were identified in kidney tissue pressed between glass slides in mallards (Anas platyrbynchos). The birds died from severe enteritis associated with blood fluke eggs, but no renal histology was described. 43 Eggs of other schistosomes may occasionally cause granulomatous ureteritis in waterfowl. 188 Parasites of the genus Renicola also may parasitize the renal tubules of several waterfowl species. 188,225 The renicolid flukes appear to have an indirect life cycle, and likely first infect mollusks and then mature in the renal tubules of susceptible species.225 Eucotylid renal flukes may reside in the dilated ducts of the renal medulla of pigeon and passerine kidneys. They seldom cause problems and their eggs may be found in the feces and confused with other fluke eggs. 98 Clinical descriptions of affected animals are poorly described.

Miscellaneous Parasites

Other parasitic diseases also may be found incidentally in the kidneys of birds. Visceral larval migrans lesions consisting of a granulomatous reaction surrounding intact or degenerate Baylisascaris procyonis larvae in the renal (and other tissue) parenchyma of the house sparrow (Passer domesticus) were noted in one study. As most of the mixed species of birds had neural larval migrans only, the renal lesions seemed comparatively uncommon.69 Chickens and pigeons have been experimentally infected with Toxoplasma gondii oocysts and evaluated for disease. While infected chickens developed no clinical signs and minimal evidence of infectivity, pigeons showed rapidly progressive disease (diarrhea, trembling, incoordination, death) and toxoplasma organisms in the kidney and other tissues. The authors stressed the importance of the pigeon crop in shedding the organisms with no emphasis on the kidneys. 18 It is probable that other parasites can affect the avian kidney and should be kept as an unlikely or rare differential diagnosis for renal disease.

Fungal

Fungal nephritis is uncommonly reported in birds. One chicken with renal and pulmonary cryptosporidiosis had Aspergillus sp. lesions in the lungs, air sacs, thoracic walls and kidneys.¹⁷⁰ In a separate study of 4-day-old chicks co-infected with Cryptosporidium baileyi and Marek's disease virus, one bird had necrotic renal aspergillosis.1 Fungal nephritis, caused by Aspergillus flavus-oryzae group, was the only lesion seen in a moribund grey-headed albatross.235 While focal coagulative necrosis, fibrous tissue and pronounced cellular reaction consisting of macrophages and multinucleated giant cells surrounding occasional fungal hyphae were noted, the lesions spared most of the renal tissue and did not account for the bird's poor condition.235 Given the close association between the air sacs and kidneys, direct extension from the respiratory system (rather than primary renal invasion) is the likely cause of the necrotic fungal lesions in the kidneys.

Nephrosis

Nephrosis is a non-specific histopathologic change characterized as any degenerative, non-inflammatory lesion of the kidney, from cloudy swelling to necrosis, whatever the cause.²¹⁴ (Figs 16.8, 16.9) This is a microscopic diagnosis that cannot be made with gross observation. Due to its role in elimination, the avian kidney is vulnerable to the effects of many chemical toxins.214 Inflammatory changes may develop, especially if the condition persists, and may confuse the diagnosis.214 It was noted that tubular lesions may be reversible if the noxious substance is removed, provided the pathologic changes are not too advanced.214 Causes of avian nephrosis have included avian malaria and hemoglobinuria, adenovirus infections, Clostridium welchii enterotoxemia, and lead, zinc, cadmium, calcium, aminoglycosides, phenoxyacid, sodium, ochratoxin A, ethylene glycol, 2,4-D, cadmium and 3-chloro-p-toluidine (avicide) toxicities. 2,14,15,16,30,55,72,125,154,161,178,214,224,242 This list is incomplete and serves only to emphasize the diversity of potential avian nephrosis-inducing agents. Although many toxins have been shown to induce nephrosis and other kidney diseases, renal lesions caused by specific toxicities are difficult to prove outside of a controlled study.

Hypertonic solutions also may cause a specific osmotic nephrosis in birds.²¹⁴ Hypertonic sucrose solutions (concentration not recorded) given intravenously have caused extensive vacuolation of the proximal convoluted tubules in birds.²¹⁴ Similar renal findings have been noted in other animals and man when injected with hypertonic sugar solutions and dextran intravenously.²¹⁴

Selected Toxic and Nutritional Diseases

Also see Chapter 4, Nutritional Considerations:

Sections I and II.

Vitamin D Intoxication

Vitamin D intoxication has been discussed in birds. 181,187 Vitamin D is converted in the liver to 25-hydroxycholecalciferol and then further hydroxylated to 1,25-dihydroxycholecalciferol in the kidney. Avian macrophages have the capacity to convert vitamin D to its active form 1,25-dihydroxycholecalciferol. 119 It is 1,25-dihydroxycholecalciferol that enhances the intestinal absorption of calcium and phosphate. 208,211

As a result of excessive calcium uptake, visceral calcinosis, nephrocalcinosis, visceral gout and urate nephrosis are considered frequent complications of vitamin D intoxication in birds. Symptoms of hypervitaminosis D include hypercalcemia, anorexia, nausea, polyuria, polydipsia, demineralization of bones, disorientation, painful joints and muscle weakness. In normal animals experimentally subjected to hypervitaminosis D, 25-hydroxycholecalciferol, and not 1,25-dihydroxycholcalciferol, increase in the serum. Chicks fed *Cestrum diurnum* leaves, which contain an analog of 1,25-dihydroxycholecalciferol, develop nephrocalcinosis and hypercalcemia, but the ultrastructural lesions are different than is noted with vitamin D toxicity.

Hypervitaminosis D & A may occur when feeding developing birds vitamin D containing supplements (Fig 16.10). A 3.5-month-old blue and gold macaw (Ara ararauna) and 5.5-month-old salmon-crested cockatoo (Cacatua moluccensis) from the same household developed polyuria, polydipsia and anorexia after being fed a diet (including supplements) with excessive vitamins A and D₃ and of calcium.²¹¹ The cockatoo was hypercalcemic and had radiographic evidence of renomegaly. Hypercalcemia, hyperphosphatemia, hyperuricemia and elevated plasma creatine kinase were noted in the macaw. The calculated levels of vitamins A (119,000 IU/kg feed) and D₃ (26,790 IU/kg feed) were over 20 times the recommended levels (5000 IU/kg feed and 1000 IU/kg feed, respectively). Vitamin D₃ is considered toxic at 4 to 10 times the recommended amount. The cockatoo died 6 days after presentation and had chronic interstitial nephritis and calcifications in the kidney, proventriculus and lung. The macaw improved gradually and became disease free after discontinuing the supplemental vitamins and minerals. Hypercalcemia was attributed to oversupplementation with calcium and the vitamin mixture.

It has been suggested that African grey parrots (*Psittacus erithacus*) may be susceptible to hypervitaminosis D,²¹¹ although no reviewed papers support this statement. Any bird species can potentially be susceptible to hypervitaminosis D.

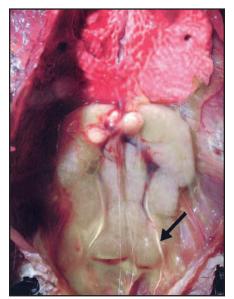

Fig 16.8 | A young adult male canary (Serinus canaria) with tubulonecrosis, mineralization and urate stasis of unknown etiology. Note the pale swollen kidneys with almost indistinct renal divisions. Urates are seen in both ureters (arrow points to left ureter).

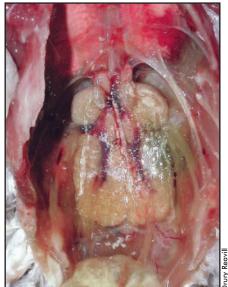

Fig 16.9 | An adult male cockatiel (Nymphicus hollandicus) with severe renal tubular mineralization and necrosis. All renal divisions are pale. The etiology is undefined.

Fig 16.10 | A young blue and gold macaw (Ara ararauna) with suspected vitamin D_3 toxicity from excess supplementation in the diet. All renal divisions are severely swollen and indistinguishable from each other. The primary histologic lesion was nephrosis.

Hypercalcinosis

High calcium intake also has been directly correlated with renal disease in birds. Broiler chicks fed 3.27% calcium in the diet for 15 weeks, starting at 18 days old, developed numerous renal lesions throughout the study. 41 Nephrosis was noted by 7 weeks and progressed to nephritis (10 weeks), visceral gout (11 weeks) and replacement of the kidney parenchyma with urate granulomas (12 weeks).41 In two separate studies, some growing chickens fed 3% calcium and 0.38% and 0.4% phosphorous, respectively, developed renal lesions such as nephritis, and ureteral and collecting duct occlusion due to probable calcium urate salts.162 Limestone sand substrate (13.48% calcium and 0.02% phosphorous) was associated with rickets and nephrocalcinosis in young ostriches. Clinically affected birds returned to normal and no new cases developed once the substrate was changed to acid-washed sand (0.03% calcium and 0.02% phosphorous).162

In a study involving young and adult budgerigars (*Melopsittacus undulatus*), increasing dietary calcium levels were shown to be more renal toxic than was excess vitamin D_3 (D. Phalen, personal communication, 2003). Parent birds were fed diets containing 0.3%, 0.7% and 1.5% dietary calcium with a range of 500, 1000, 1500 and 3000 IU of vitamin D_3 per kg/feed. The adults subsequently fed the young the same diet. When fed a diet containing 3000 IU of vitamin D_3 per kg/feed, there was a questionably increased mortality rate only in the birds receiving 1.5% dietary calcium. However, there was a

clear correlation with mild and severe metastatic (renal) mineralization in birds fed 0.7% and 1.5% calcium, respectively. The young birds fed 0.7% and 1.5% calcium died by 24 to 32 days old and never fledged (32 to 35 days). Growth rate and hatchability were poor only in the groups fed 1.5% calcium. While only a few adults died by 5 months on diets containing 1.5% calcium, most had metastatic renal mineralization when fed 0.7% calcium. Birds fed 0.3% calcium had no evidence of metastatic mineralization, and had good hatchability and growth rates (D. Phalen, personal communication, 2003). This study suggests that some species, such as budgerigars, may be very sensitive to dietary calcium levels and that supplementation should be used cautiously.

Hypovitaminosis A

Hypovitaminosis A also may lead to renal disease in avian patients. In birds with hypovitaminosis A, the ureters and renal collecting ducts may undergo metaplasia, changing the normal double-layered epithelium to keratinized stratified squamous tissue.²¹⁴ These epithelial changes can result in decreased mucin production and excessive keratin leading to plug formation and ureteral obstruction.²¹⁴ The consequential (secondary) lesions include renal tubular dilatation and necrosis, tophus formation and interstitial fibrosis.²¹⁴ Nephrosis, nephritis, visceral gout and severe replacement of the kidney parenchyma by urate granulomas were noted in broiler chicks fed vitamin A-deficient diets for 15 weeks starting at 18 days old.⁴¹ See Chapter 4, Nutritional

Considerations: Section II, Nutritional Disorders, for Hypervitaminosis A.

High-Cholesterol Diets

Cholesterol supplemented in the feed can induce significant renal disease in pigeons.121 Crystalline cholesterol and 10% lard were added to the diets of these pigeons under experimental conditions. The kidneys of some affected birds are firm, diffusely off-white, have an irregular capsular surface and may be enlarged up to 3 times their normal size. All renal components are susceptible and lesions may include tubular degeneration and dilatation, glomerular hypercellularity and hypertrophy (proliferative glomerulopathy), periglomerular fibrosis, lipidladen cells within the glomeruli and multifocal, acute intersitial nephritis. 121 Since only mortality and necropsy results were reported, clinical information such as diagnosis and management/treatment were not provided. However, this does bring up the potential complication of feeding some birds high-cholesterol foods.

High-Protein Diets

High-protein diets have been associated with renal disease in birds, but only under specific conditions. Compared to a low-protein diet group, pigeons fed a high-protein diet had an observed increase in drinking rates and urine production.¹⁵³ Unfortunately, too little information was present to draw any conclusions relating dietary protein to renal disease. It has been shown that feeding 18-day-old broiler chicks a 42.28% protein diet for 15 weeks did induce multiple renal abnormalities (primarily nephrosis and visceral gout).41 Extraordinarily high protein levels in the diet of genetically predisposed chickens have been shown to cause gout, but a direct relationship with renal disease has not been established. A more detailed discussion of the effects of dietary protein and hyperuricemia are discussed under Part 2: Serum or Plasma-based Biochemistries, Uric Acid, and Part 2: Dietary Modification, Protein.

Diets high in urea also have been linked to nephritis outbreaks in poultry. 42 Fish meal adulterated with urea was linked to high (6-8%) mortality in two separate farms. Clinically affected birds had gross lesions that ranged from pale nephromegaly and hepatosplenomegaly to urolithiasis and visceral gout. Histologic lesions ranged from interstitial, perivascular and pericapsular nephritis to proliferative glomerulopathy, and severe tubular and glomerular atrophy and fibrosis in severe cases. The disease was termed "nephritis-nephrosis syndrome in poultry" and was eliminated when the ureaadulterated feed was replaced with a different balanced diet. 42 See Chapter 4, Nutritional Considerations for more on protein levels in birds.

"Diet-Induced Renal Disease of Color Variety Psittacine Birds"

Although not formally entered into the veterinary literature, there appears to be a form of renal disease induced by feeding predominately pelletized diets to various color variety psittacine birds (M.S. Echols, unpublished data). All affected birds observed by the author have been color variety cockatiels (Nymphicus hollandicus), lovebirds (Agapornis spp.), budgerigars and parrotlets (Forpus spp.) and have eaten a predominately commercial pelletized diet. As most of the major brands of commercial pelletized diets have been involved, there appears to be no predilection toward any one manufacturer's product. With the exception of a history of predominately commercial pelletized diet, affected birds do not display any characteristics pathognomonic for "diet-induced renal disease." Of the birds with suspected "diet-induced renal disease," in which the kidneys have been histopathologically examined (pre- and postmortem), lesions have been limited to non-specific tubular nephrosis and were reversible after feeding a non-pelletized diet for 1 to 3 months. The diet should be converted to one appropriate for the species being treated.

Mycotoxic Nephropathy

Mycotoxic nephropathy, due primarily to ochratoxin A, has been reported in chickens and ducks. 63,149,224 Ochratoxin A is produced by several species of Aspergillus and Penicillium. 149 Ochratoxicosis occurs primarily because of ochratoxin A buildup in chick feed stored under conditions of excessive moisture, and has been identified from moldy feed, rice, groundnuts and foods prepared from these materials. 149,157,224 Ochratoxicosis causes liver and kidney damage, and specifically induces degeneration and vacuolation of hepatic cells and distension, enlargement and hypertrophy of renal proximal convoluted tubules, respectively.⁶³ Because of the multiple potential sources of the toxin, it is reasonable to assume that multiple avian species, other than chickens and ducks, can be exposed to and damaged from ochratoxin.

Other mycotoxins also have been closely correlated with renal disease in birds. Oosporein, a toxic pigment produced by Chaetomium trilaterale, C. aureum and several other species of filamentous fungi, is considered to be primarily a renal toxin.184,185 The importance of oosporein is that the toxic isolates have been found in various agricultural commodities such as animal feeds, cereal grains and food products. Moldy corn in particular, growing C. trilaterale, may yield high concentrations of oosporein toxin. In studied young broiler chickens and turkey poults, oosporein toxicosis is dose-dependent and can cause dehydration, stunted growth, pale nephromegaly and death, and appears to severely affect uric acid secretion leading to hyperuricemia and visceral

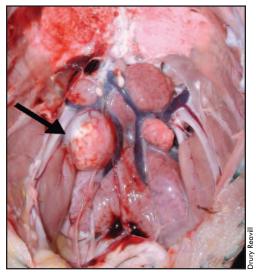

Fig 16.11a | A young male hyacinth macaw (Anodorhynchus hyacinthinus) has a large renal cyst (arrow) deforming the right middle renal division.

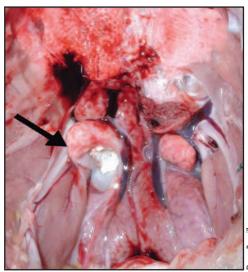

Fig 16.11b | The cyst (arrow) is opened, revealing a white, pasty interior.

and articular gout.¹⁸⁴ Although still severely affected, turkey poults seemed to tolerate higher doses of oosporein before toxicosis was apparent than did broilers, bringing up the issue of physiological differences between these two species.¹⁸⁵ Sterigmatocystin (STG) is produced by multiple fungal species and has caused acute liver and renal disease and death in 10- to 12-day-old leghorn chicks.²²² Chicks given intraperitoneal STG developed tubular nephrosis and hepatic necrosis and died within 21 hours of injection.²²²

Lead Nephropathy

Lead toxicity is the most common cause of metal poisoning in waterfowl and affects a wide variety of other bird species. ¹⁵¹ Although neurological and gastrointestinal clinical signs are usually seen, lead can have severe effects on avian kidneys. Renal lesions may include proximal tubular necrosis and degeneration (nephrosis), visceral gout and, in some birds, acid-fast intranuclear inclusion bodies. ⁵⁵ Kidney, liver and brain tissue concentrations of 3 to 6 ppm wet weight are suggestive and greater than 6 ppm is diagnostic for lead poisoning. ¹²⁵ Also see Chapter 31, Implications of Toxic Substances in Clinical Disorders and Chapter 17, Evaluating and Treating the Nervous System.

Congenital and Hereditary Defects

Multiple congenital renal defects are reported in birds.^{214,238} Heritable renal diseases such as X-linked hereditary nephritis in Samoyed dogs and Alport's syndrome in humans are discussed in many mammals, but are poorly described in the current avian literature.¹⁰⁰ In some large poultry flocks, up to 20% of the necropsied birds have had evidence of "faulty kidneys" consid-

ered to be congenital in nature. 238 Reported renal abnormalities include complete or partial kidney agenesis, ureteral dilatation, structural glomerular changes and predilection toward hyperuricemia (due to presumed proximal tubule defects). 9,214,238 Renal cysts are occasionally seen and may be congenital or acquired188 (Figs 16.11a,b). Polycystic renal disease has been noted in chickens, pigeons and a bald eagle (Haliaeetus leucocephalus).228 Renal agenesis is the most frequently described inherited defect and has been attributed to a simple recessive gene with variable penetrance in brown leghorn chickens. 214 With partial renal agenesis, the cranial renal division is most likely affected.214 Although birds usually die with neurological signs or massive interrenal hemorrhage, emus (Dromiceius novaebollandiae) with inherited neuronal storage disease (gangliosidosis) develop unusual large vacuoles in the renal tubular epithelial cells of the proximal convoluted tubules.¹⁷ Congenital renal diseases have been reported in chickens, pigeons, quail, a canary and a mandarin duck but likely exist in numerous other species. 187,214,238

Fatty Associated Diseases

Lipids are not histologically evident in normal avian renal tissue, but may be noted under certain pathologic circumstances. ²¹⁴ Fasting (water and food) may result in reversible lipid deposition within the renal tubular epithelium. ²¹⁴ Defects in lipid metabolism or storage also may account for renal tubule cell lipidosis. ¹⁸⁷

The now rare fatty liver and kidney syndrome of broiler flocks and turkeys (due to biotin deficiency) can cause heavy lipid accumulation within the proximal convoluted tubules.^{214,247} At necropsy, the liver, kidneys and

sometimes other organs are often pale and swollen with deposition of sudanophilic lipid droplets.²⁴⁷

A fatty liver-kidney syndrome also has been reported in merlins (Falco columbarius). 48,72 Only captive birds have been affected. 48 Most affected merlins have been approximately 5% above normal body weight and fed a diet predominately of day-old chicks for several months prior to death. Most affected merlins died suddenly either while eating or with the keeper. A few became lethargic a few hours before death. 48 As is seen in broiler chicks, merlins with fatty liver-kidney syndrome develop excess fat in the liver, kidneys and spleen. One-day-old (feeder) chicks contain appreciable avidin, which may bind dietary biotin, in turn leading to (a theoretical) biotin deficiency. Biotin and other deficiencies, high-fat diet, hepatic anoxia and various toxic agents, have been proposed as causes of fatty liver-kidney syndrome of merlins, but a definitive etiology has not been confirmed.72

Neoplasia

The avian kidney, just as with other animal tissue, is susceptible to neoplastic conditions. Nephroblastomas are the most commonly reported avian renal tumor.214 Nephroblastomas and renal adenocarcinomas comprise the majority of kidney tumors in budgerigars (Melopsittacus undulatus). 173,187 Renal carcinomas are the most frequently reported tumor of the urinary system in nondomestic free-ranging and captive birds. 130 Malignant renal tumors are more commonly seen in males than females and are more commonly observed in psittacine than passerine species.⁷⁹ In one study of 74 budgerigars suspected of having coelomic tumors, one-legged lameness and abdominal enlargement were the primary clinical signs. In the same study, 47 birds (63.5%) had renal tumors and were diagnosed most commonly within 5 years of age.173

Lymphoid, myeloid and erythroleukemias, lymphoma, ovarian, liver and oviductal adenocarcinomas, hemangioma, lipoma, histiocytic cell sarcoma, neurofibroma, granulosa cell tumor, cystadenoma with bone, squamous cell carcinoma, unclassified carcinoma and osteogenic sarcoma have all been reported either as primary or secondary renal neoplasms in birds. 121,193,214,241

Like other cancers, there are likely many causes of renal tumors in birds, but there is little information regarding definitive etiologies. Avian leukosis virus (ALV) can induce renal tumors in chickens. While ALV has been found in budgerigars with renal tumors, a definitive association has not been made.¹⁷³

A common presentation with renal cancer is unilateral to bilateral leg weakness or paralysis and slight ataxia.²⁴¹

Other clinical signs may vary, but often include diarrhea, dyspnea, abdominal distension and weight loss. 130,241

The lumbar plexus lies dorsal to the cranial renal division, while the sacral plexus runs through the middle division parenchyma. Because of this close association, any parenchymal inflammation or pressure on or from within the kidney can potentially result in nerve dysfunction and resultant lameness. Additional neoplastic extension to the overlying spinal column also may result in nerve dysfunction. Peripheral neural compression should result in peripheral neuropathy with eventual loss of the withdrawal reflex, not seen with most spinal cord lesions. In addition to lameness and muscle atrophy, ipsilateral osteopenia was noted in a cockatiel (*Nymphicus bollandicus*) with a renal adenocarcinoma.

Unfortunately, avian renal tumors carry a poor prognosis. In reported cases of renal cancer, most birds lived less than 3 months following diagnosis.⁷⁹ It has been stated in reference to budgerigar renal tumors that the course of the disease may take weeks to several months.²⁴¹

Urolithiasis and Ureteral Obstructive Disease

In birds, urolithiasis refers to the formation of large urate "stones" in the ureters, is primarily seen in pullets and caged laying hens, and can result in increased mortality and decreased egg production.⁵⁰ Urolithiasis has been reported primarily in the poultry literature on numerous occasions, but is rarely described in other avian species.^{20,42,214,251}

Common findings include atrophic ipsilateral renal tissue, a normal to hypertrophic (compensatory) contralateral kidney and a dilated ureter obstructed with one or more urate stones. 20,214,251 Histologic lesions noted with urolithiasis have included glomerular nephritis, tubular nephrosis, ureteritis and pyelonephritis with interstitial mononuclear infiltrates.50 One study noted that virtually every cull hen or out-of-production hen examined at affected layer complexes (sites with high incidences of urolithiasis) had gross kidney lesions and kidney stones.50 In birds, ureteral obstruction (as may occur with ureteroliths, cloacal masses, urodeal fold thickening, etc) may cause a postobstructive form of renal disease. Simple ligation of a bird's ureter results in ipsilateral renal atrophy and this result is similarly expected with urolithiasis.214 Naturally occurring ureteroliths in chickens are known to contain uric acid, urates, calcium and ammonia. 148 These statements suggest that the kidney should be closely evaluated (eg, via biopsy) when urolithiasis is present.

The cause of urolithiasis in poultry flocks has not been definitely identified.²¹⁴ However, it is known that coronavirus-associated nephritis in pheasants can induce inter-

stitial nephritis, tubular dilatation, ureteral impaction and subsequent visceral gout. ¹⁸⁶ In addition to infectious bronchitis virus infection (IBV — a coronavirus), other proposed causes of urolithiasis in poultry include water deprivation, excess dietary calcium and nutritional electrolyte imbalances. ⁵⁰ One group reported that by changing the form of calcium from small particle size to flakes, adding additional phosphorous and by modifying the IBV vaccination protocol, the investigators were able to significantly reduce the incidence of urolithiasis in a previously affected layer flock. However, they could not determine which management change resulted in the beneficial effect. ⁵⁰

Urolithiasis in psittacine species is rare, but has been reported. A 21-year-old male double-yellow headed Amazon parrot (Amazona ochrocephala) with a lifelong history of straining to void and chronic intermittent vomiting for a "few years" was diagnosed with septic ureteral fluid and ureterolithiasis.56 Dorsocaudal coelomic radiodense opacities were noted on screening radiographs, but the diagnosis was ultimately made via exploratory celiotomy. Multiple surgeries were required to remove the stones. A kidney biopsy was not collected and a relationship to renal disease could not be made. The ureteroliths were composed of monosodium uric acid crystals and proteinaceous material mixed randomly or forming irregular laminae. Although the bird had dry, flaky skin, a urate-pasted vent, dull feathers and heterophilic (28,840 cells/µl) leukocytosis (32,000 cells/µl), the authors concluded that the clinical signs associated with ureterolithiasis in this bird were non-specific and may result in delayed diagnosis.⁵⁶ The cause was not determined.

Amyloidosis

Amyloidosis is occasionally noted in association with avian renal disease. Amyloid deposits are often related to chronic inflammatory disease and usually found systemically, but can affect specific tissues.²⁹ Typically, amyloid presents histologically as amorphous, eosinophilic, homogenous material that stains red-orange with Congo red and bright green when examined under polarized light. Amyloidosis is most frequently noted in captive Anseriformes (geese, ducks, swans), Gruiformes (cranes) and Phoenicopteridae (flamingos), but also has been reported in numerous other species.^{127,201} See Chapter 15, Evaluating and Treating the Liver for a discussion of amyloidosis.

There are a few reports of amyloidosis involving the kidneys of birds. Multifocal amyloidosis was noted in a diamond firetail finch (*Stagnopleura bella*) with proventricular cryptosporidiosis, and was found specifically in the glomeruli and interstitial tissue around the tubules.¹⁹ Numerous laying Japanese quail with systemic amyloido-

sis had amyloid deposits in the renal tubules and no to minimal deposition in the glomeruli.171 While some of the birds had concurrent inflammatory diseases such as egg yolk peritonitis, the etiology of the amyloidosis was not determined.¹⁷¹ Four days after acute onset illness, a roseate flamingo (Phoenicopterus ruber) died with necrogranulomatous and septic air sacculitis, perihepatic serositis and hepatic capsulitis, hemosiderosis, atherosclerosis and systemic amyloidosis.29 The renal amyloid involvement was severe, resulting in a marked glomerulopathy and was likely the cause of death.29 Amyloid was found within the connective tissue of mycobacterial tubercles found on the kidney surface of a hooded merganser (Lophodytes cucullatus). No details were given regarding the premortem disposition of the bird.²⁰⁹ The author has noted renal amyloidosis in pet geese. These birds presented in end-stage renal failure and necropsy showed severe renal amyloidosis. The underlying cause was never elucidated.

Renal Hemorrhage

Renal hemorrhage is sporadically reported in the literature and may exist predominantly as a secondary finding. Sudden death syndrome (SDS), also known as "perirenal hemorrhage syndrome," is the main cause of death in heavy turkey flocks from 8 to 14 weeks of age.24 Primarily male turkeys in good body condition die acutely with SDS and typically have characteristic postmortem lesions including perirenal hemorrhage and organ congestion including the lungs, spleen and liver. 24,75,129 One group noted that most affected birds had hypertrophic cardiomyopathy and proposed that acute congestive heart failure was the cause of death and severe passive congestion accounted for the perirenal hemorrhage. 129 The cause is still unknown, but other theories include severe lactic acidosis and limited cardiac capacity, noted in predisposed turkeys, as contributing factors.24

An adenovirus, new gosling viral enteritis virus (NGVEV), has been shown to cause renal hemorrhage and hyperemia 4 days postinfection in newly hatched goslings. 44 Renal tubular and ureteral epithelial cell degeneration and intestinal glandular epithelial cell necrosis and sloughing also were consistently seen in the goslings infected with the rapidly progressive NGVEV.44

Hydropericardium syndrome of broiler chickens is a contagious disease caused by an adenovirus and can result in grossly swollen kidneys with extensive renal hemorrhage and hydropericardium.² Three- to six-week-old broilers are typically affected and mortality ranges from 10 to 60%. Renal tubular nephrosis and necrosis within the liver, spleen and bursa of Fabricius may be seen microscopically.²

Other causes of renal hemorrhage also may be seen. Simple trauma, such as from an animal bite or endoscopic biopsy, may result in renal hemorrhage. If the renal capsule is left intact, a subcapsular hematoma may form, increasing the renal size and possibly placing pressure on the neighboring nerve plexi.134 Renal petechial hemorrhage resulting from Clostridium perfringens toxemia was reported in a rock partridge (Alectoris graeca). 134

Metabolic Renal Disease

Metabolic renal disease includes dehydration, diabetes mellitus, amyloidosis, gout and lipidosis, the latter three of which have already been discussed. Diabetes mellitus has been noted in a variety of birds and is seen with polyuric, polydipsic glucosuria and hyperglycemia.²²⁸ Descriptions of the gross and microscopic effects of diabetes mellitus on avian kidney tissue were not found.

One of the more common metabolic derangements associated with renal disease is dehydration. In chickens, dehydration has been associated with nephrosis characterized by tubular dilatation, with or without proteinaceous casts, epithelial necrosis and rare urate granulomas or casts. 198 Food restriction during dehydration may lessen the nephrosis lesions. 198

Gross Renal Changes

Gross renal changes including masses, discolorations, and size and shape alteration are non-specific and should be cautiously interpreted.

Differential diagnoses for renomegaly include neoplasia, inflammation (including infectious and non-infectious diseases), cystic formation, ureteral obstruction, toxic changes, metabolic disorders (including dehydration, gout, lipidosis) and congenital abnormalities. 79 Also, non-pathological increase in kidney size has been noted in chickens fed certain dietary precursors such as inosine that increase plasma uric acid levels.215 In these chickens, the renal enlargement was likely due to the increase in processing of uric acid in the kidney.²¹⁵ Renal and ureteral calculi also may be noted.

Postmortem Renal Change

Renal postmortem changes are noted in chickens as soon as 22 minutes following death at 37° C (98.6° F). 163 Early renal postmortem changes occur in the proximal tubular epithelium, followed by collecting tubule epithelium and glomerular nuclei. 163 Even with cooling to 4° C (39.2° F), proximal tubular changes can be observed within 45 minutes of death. The early postmortem proximal tubular changes can be confused with antemortem proximal tubular degeneration and should be interpreted with caution. 163 In effort to decrease postmortem changes, perform a necropsy and fix tissues as soon after death as possible.

PART 2: A Review of Diagnosis and Management

HISTORY AND PHYSICAL **EXAMINATION**

A historical review of a bird's environment, diet, source, exposure to infectious agents and toxins, genetics and behavior becomes important for both diagnosis and management of avian renal disease. Environmental factors can include exposure to known aerosolized, ingested or topical toxins. Adverse conditions that might lead to dehydration or other stresses also may be identified. The diet should reflect what is appropriate for that species, and the history should include any additional dietary supplementation or changes. Understanding the bird's origin, whether from a specific aviary, store, quarantine station, the wild, etc, may suggest the possibility of problems seen in other avian species from the same source. Known exposure to infectious agents (and again, toxins) is especially important, as definitive diagnosis of bacterial, viral, parasitic, fungal and toxic agents is not always possible without cultures, special stains, electron microscopy, in situ DNA hybridization, PCR probes or other diagnostics. Genetic problems are poorly described in birds, but with intense inbreeding, development of mutations or conservation breeding efforts from an extremely limited gene pool, it is reasonable to assume that hereditary defects will become more common. Behavioral changes including depression, anorexia, anuria, oliguria, polyuria, polydipsia, feather picking over the synsacrum, self-mutilation, seizures and others may be associated with renal disease and should be noted in the history.¹⁸¹

Most physical examination abnormalities associated with avian renal disease are non-specific, but there are some key findings that tend to warrant further investigation. It is highly likely that a bird with articular gout has had or currently has some form of renal disease. For this reason, consider renal biopsy in some birds with articular gout to help rule out or specifically identify kidney disease. Not all birds afflicted with articular gout, however, have renal disease. Unilateral leg lameness or paresis may accompany renal disease. This is particularly true if kidney disease causes inflammation or compression on the lumbar and/or sacral nerve plexus that is so intimately associated with the dorsal renal parenchyma. Birds with renal disease also may exhibit dehydration,

generalized weakness, regurgitation and decreased muscle mass with or without historical anorexia, all of which are non-specific signs.¹⁶⁶

DIAGNOSTIC TESTS

Multiple diagnostic tests are available to help clinicians identify and define multiple disease processes in birds. As diagnostic technology improves, so will our ability to accurately diagnose diseases in birds. The tests listed below are ones that are most frequently discussed or used in diagnosing renal disease in birds. See Table 16.3 for reported selected plasma-based diagnostics sometimes used in diagnosing renal disease in birds. Many diagnostics such as fecal floatation, which help diagnose renal coccidiosis, are not discussed, but should be included in a minimum database when evaluating sick birds. Some new or unfamiliar diagnostics also are introduced.

Considering all the diagnostic tests available, the author has noticed a pattern of laboratory abnormalities that is often strongly correlated with many forms of renal disease in birds. This includes persistently elevated uric acid (at least two consecutive tests on a well-hydrated and fasted bird), elevated creatinine phosphokinase (CPK), mild anemia and a relative heterophilia with or without a total heterophilia. Elevated CPK is a very nonspecific indicator of multiple types of tissue damage and is not mentioned further. Using the currently available diagnostics, the actual type and degree of renal disease can be confirmed only with a kidney biopsy.

Complete Blood Count (CBC)

Some non-specific CBC changes may be associated with avian renal disease. A marked (relative) heterophilia was noted in two chickens with urolithiasis, but no total white blood cell count was given.20 Heterophilia, monocytosis, lymphopenia and normocytic-normochromic anemia were noted in broiler chicks with various forms of histologically confirmed renal disease, but specific details were not given. 41 In a different study in chickens, clinically affected birds with histologically identified nephritis had significant heterophilic leukocytosis when compared to "normal" birds. 42 The author has reported that many pet birds (geese, doves, various psittacine birds) with different forms of renal disease have demonstrated a mild to marked relative heterophilia with a normal total white blood count. 47,64,65 These changes are non-specific, however, and can be seen in healthy birds under stress alone.221

Serum or Plasma-based Biochemistries

Selected plasma biochemistries may provide several useful clues toward renal disease in avian patients. Although many serum and plasma-based tests may be "abnormal"

Table 16.3 | Selected Plasma-based Diagnostics in Birds

Table 10.5 Selected Flashia-based Diagnostics in Diras					
Diagnostic Test	Species	Normal Range	Reference(s)		
Uric Acid	Pigeon	94-518 μmol/L, 225-574 μmol/L	87, 138, 141		
	Peregrine falcon	253-996 μmol/L, 4.3-16.7 mg/dl			
Urea	Pigeon	0.36-0.64 mmol/L, 0.27-0.94 mmol/L	87, 138, 141		
	Peregrine falcon	0.8-2.9 mmol/L, 2.2-7.0 mg/dl			
Creatinine	Pigeon	23.7-32.3 μmol/L, 20-56 μmol/L	87, 141		
	Peregrine falcon	24-64 μmol/L, 0.27-0.72 mg/dl			
Urea/Uric Acid	Pigeons	1-3 138, 14			
	Peregrine falcon	1.7-6.4			
Osmolality	Pigeon	299.4-312.6	138, 141		
(mOsm/kg H ₂ O)	Peregrine Falcon	322-356			

Reference values for the pigeon (Columba livia domestica) and peregrine falcon (Falco peregrinus) are included. These reported values are highlighted because of their potential use in identifying renal disease and dehydration.

in birds with renal disease, only specific diagnostics are covered.

Uric Acid

Plasma uric acid can be useful as a screening tool for advanced renal disease. With the exception of gastrointestinal uricolysis, uric acid and its salts (urate) are the end product of nitrogen metabolism in birds. 9,60,132,214,246 Elevated uric acid has been correlated with histologically confirmed severe renal disease in chickens (tubular nephrosis and interstitial nephritis).224 In a separate study involving dehydrated chickens, increased serum uric acid was associated with histologic renal lesions. 198 Broilers given oosporein (renal toxin), developed visceral and/or articular gout, swollen, pale kidneys and had a 48% increase of uric acid over control birds. 184 In a similar study with oosporein in turkey poults, intoxicated birds had dose-dependent increases in uric acid (over controls) ranging from 76 to 140%. 185 It was noted that fasting hyperuricemia (>16.7 mg/dl [>1000 µmol/L]) in peregrine falcons (Falco peregrinus) indicates renal failure.141

Uric acid is produced and secreted in the avian liver, kidney and pancreas. 46,106 Although produced predominately in the liver, at least 17% of the uric acid found in chicken urine may be synthesized in the kidney. 46 Specifically, nephrogenic uric acid synthesis may increase when plasma purine precursors are elevated. 46 These findings suggest the avian kidney has an important role in the synthesis, in addition to elimination, of uric acid, especially when increased precursors are available. 46 Precursors, including body proteins degraded because of poor nutritional status, have been suggested as a cause of elevated uric acid and should be considered in birds with hyperuricemia. 155

An interesting secondary role of uric acid in birds is its antioxidant capability. In chickens, it has been clearly shown that plasma uric acid concentrations are inversely correlated with oxidative activity.²¹⁵ It has been stated that uric acid constitutes one of the most important antioxidants in birds and is directly linked to their longevity.²¹⁵

Uric acid is cleared mainly via tubular secretion and is largely independent of glomerular filtration, water resorption and urine flow rate. 9,140,141,187,195 Blood uric acid levels are mildly affected by a bird's hydration status, but rather reflect the functional capacity of the renal proximal tubules. 187 However, in a study with dehydrated chickens, uric acid levels increased after 24 to 48 hours of water restriction, but only in those birds allowed free access to food. 198 Serum uric acid levels actually dropped within 24 hours in birds denied food and water. 198 It has been estimated that renal function must be below 30% of its original capacity before hyperuricemia develops. 166 Suggested normal avian uric acid levels range from less than 1 to 10 mg/dl (59.48-594.8 μ mol/L). 214

Hyperuricemia is defined as "any plasma uric acid concentration higher than the calculated limit of solubility of sodium urate in plasma." In bird plasma, this theoretical limit of solubility of sodium urate is estimated to be $600 \, \mu \text{mol/L} (10.8 \, \text{mg/dl}).^{143}$

In chickens, the uric acid renal tubule transport system does not appear to become saturated until plasma uric acid levels exceed 60 mg/dl (3569 μ mol/L)° which demonstrates the lack of clarity in the literature and experimental dosages.° Chickens genetically predisposed to hyperuricemia and fed high-protein (60%) diets develop an elevated steady state of plasma uric acid (10-60 mg/dl {59.48-3569 μ mol/L}) in order to excrete their daily loads of this by-product.° The increased basal plasma uric acid made the affected chickens susceptible to articular gout formation.° One group suggested that these chickens genetically predisposed to gout had a defective uric acid transport mechanism at the peritubular membrane. ¹⁸⁴

Uric acid represents 80% or more of the nitrogen excreted by birds. 9.214 Therefore, a significant increase in the proportion of nitrogen excreted as uric acid is not likely, even with increased dietary protein consumption. At least in chickens, hyperuricemia is likely due to reduced renal tubular secretion of uric acid and not excessive production as can occur in humans. 9.214 These findings imply that renal tubular diseases are likely responsible for hyperuricemia, and uric acid abnormalities may not be evident until very high-protein diets are fed. Specifically in chickens, dysfunctional proximal convoluted tubules result in reduced urate secretion and can lead to hyperuricemia if severe. 214

In birds of prey, uric acid production is directly related to the amount of protein consumed and transient rises are noted following high-protein meals. 140,143 Peregrine falcons (Falco peregrinus) and red-tailed hawks (Buteo jamaicensis) are reported to have a "significant" postprandial increase in plasma uric acid concentration (hyperuricemia) for up to 12 hours after ingesting a natural meal. 140,143 The significant postprandial uric acid increase noted in peregrine falcons was up to 32 mg/dl (reported as 1881 µmol/L) between 3 and 8 hours after being fed.143 It has been stated that significant postprandial increases in both urea and uric acid persist for up to 15 hours in peregrine falcons. 143 It was not clear why these birds of prey did not develop gout lesions, but the authors recommended a 24-hour fast prior to evaluating serum uric acid in peregrine falcons.143 The authors further recommend that a 24-hour fast should be considered for all carnivorous avian species prior to blood uric acid testing. Almost identical findings of postprandial hyperuricemia were noted in blackfooted penguins (Spheniscus demersus) and represent another species that should be fasted before measuring uric acid levels. 122

Uric acid production following a high-protein meal has been studied in various psittacine birds. In one study with African grey parrots (Psittacus erithacus sp.), plasma uric acid concentrations showed a positive correlation with dietary protein consumption. 105 However, even though the fed protein level was as high as 30%, plasma uric acid levels remained within normal ranges. 105 In cockatiels fed 11, 20, 35 and 70% protein for 11 months, serum uric acid increased linearly with dietary protein levels.¹²³ However, the serum uric acid level was significantly greater only in birds fed 70% protein diets. Because no histologic or gross renal lesions were found at necropsy, the authors concluded that the rise of uric acid was related to dietary protein concentration and not kidney damage.123 It was found that feeding diets containing 13.5, 18.2 and 24.6% protein for up to 24 weeks had no effect on serum uric acid levels in parakeets.8

In consideration of the above-described causes of elevations in uric acid, this single biochemistry value can help identify significant renal disease. The author prefers to repeat (fasting) uric acid levels on well-hydrated birds before a suggestion of renal disease is made. In birds with suspect renal disease that have a single laboratory value of hyperuricemia, the author will often give a total of 100 ml/kg SQ, SID to BID of isotonic fluids for 2 days and then recheck the uric acid level. In the author's experience, birds with persistent hyperuricemia after fluid therapy and/or fasting have some form of renal disease.

Urea

Unlike mammals, urea in birds is produced only in small

amounts (by renal mitochondrial breakdown of arginine) and does not serve as the end product of protein metabolism.187 Plasma urea in birds is excreted by glomerular filtration and, unlike uric acid, blood urea concentrations are more significantly affected by the bird's hydration status. 138,140,187 During normal hydration, filtered urea is 100% excreted but is 99% reabsorbed in the tubules during dehydration. 138,141 Plasma urea also has been shown to significantly increase in peregrine falcons for up to 15 hours postmeal.143 In studied cockatiels, serum urea levels increased linearly with dietary protein levels (11, 20, 35 and 70%). 123 Separate studies involving the domestic fowl and pigeons demonstrated decreased urea elimination and/or increased blood urea levels (6.5- to 15.3-fold increase in pigeons) in dehydrated birds. 138,187 It has been shown that plasma urea nitrogen increased in a dose-dependent fashion (in turkeys) at every level of dietary oosporein (nephrotoxin). 185 These intoxicated turkey poults also were showing signs of dehydration.185 It has been proposed that plasma urea is the single most useful indicator of prerenal (dehydration) causes of kidney failure in birds. 140

The urea:creatinine and urea:uric acid ratios can be used to better define pre- and postrenal azotemia. Because reabsorption of urea is disproportionally higher than both creatinine and uric acid, these ratios should be high during dehydration and ureteral obstruction. The formulas for these ratios are listed below:

Urea:creatinine = $\frac{\text{urea (mmol/L)} \times 1000}{\text{creatinine (}\mu\text{mol/L)}}$

Urea:uric acid = $\frac{\text{urea (mmol/L)} \times 1000}{\text{uric acid (}\mu\text{mol/L)}}$

Creatinine

Birds produce little creatinine from its precursor, creatine. ¹⁶⁶ Creatinine is eliminated by tubular secretion but clearance is variable. ⁸¹ Clinically, creatinine may be elevated in pet birds by feeding high-protein diets. ⁸¹ It was shown that plasma creatinine also will increase significantly in dehydrated pigeons. ¹³⁸ The relationship between creatine and creatinine in birds with renal disease is poorly understood, and differentiation does not appear to be useful clinically. ^{81,166,181}

Proteins

Although hypoproteinemia has been noted as being associated with renal failure, few studies have evaluated serum protein levels in birds with renal disease. He Biochemically determined low serum protein has been noted in chickens with advanced tubular nephrosis and interstitial nephritis. He two chicken flocks with spontaneously occurring urolithiasis, plasma protein level changes (method of determination not disclosed) were not significantly associated with renal disease. Me He State Popular Popu

affected birds developed articular and/or visceral gout, gross renal changes and death, broilers intoxicated with oosporein (fungal nephrotoxin) had, with the exception of one group, no significant changes in plasma protein (biuret method) over the normal (control) birds. 184 A single group of broilers receiving a midrange amount of oosporein had a statistically significant rise in plasma protein over controls. The cause for this single discrepancy was not determined.184 In a similar study using oosporein-intoxicated turkey poults, statistically significant decreased albumin:total protein was noted at all levels of intoxication over controls, but total protein remained unchanged and albumin was not significantly decreased until the highest levels of the toxin were given. 185 These few studies show a couple of important facts: there is limited information properly associating plasma proteins with renal disease, and differing species may have dissimilar plasma protein levels under similar disease conditions. As discussed under Part 2: Electrophoresis, Plasma Protein Electrophoresis, protein levels should be evaluated electrophoretically (in addition to the more common biochemical methods).

PLASMA ELECTROLYTES

The effect of renal disease on plasma electrolytes is poorly studied in birds. Hyperkalemia and hyperphosphatemia have been loosely associated with renal failure, but studies are limited in birds.141 No significant associations between renal disease and plasma sodium, potassium, calcium, magnesium, chloride and phosphate levels were noted in birds from two chicken flocks with spontaneously occurring urolithiasis. 20,251 Specific sample collection/storage was not discussed and the authors conceded that their handling of the samples might have affected the results.20,251 Dehydrated chickens allowed free access to food developed significantly elevated serum sodium and phosphorous by 24 hours and after 24 hours, respectively, but maintained normal potassium levels.198 Histologically, these chickens had mild renal tubular dilatation.198 Turkey poults intoxicated with oosporein (nephrotoxin) developed significantly decreased plasma potassium and phosphorous, and had no changes in sodium compared to controls. 185 As the avian kidney is responsible for electrolyte regulation, it is reasonable to assume that electrolyte disorders can be present in birds with renal disease.

MICROBIOLOGIC ANALYSIS

Microbiologic assays may be useful in identifying infectious causes of avian renal disease. Bacteria may enter the renal system either hematogenously, ascending from the ureters and cloaca, or as an extension of surrounding organ infection.¹⁸⁷ The avian coccygeomesenteric vein drains the mesentery of the hindgut into the

hepatic portal and/or the renal portal vein.226 It is conceivable that colitis may serve as a hematogenous source of infectious agents, toxins and inflammatory products to the kidney if blood flow draining the colon is diverted into the renal vasculature. For this reason, collection of a cloacal or fecal microbial culture is a rational portion of the supportive laboratory database in birds with suspected renal disease. Severe ulcerative colitis caused by Salmonella infection resulted in ascending bacterial nephritis in four African grey parrots. 187

Bacterial nephritis in birds is often a component of systemic infection and multiple organs may be involved. 187 In one study, 50% of birds with systemic bacterial infections had kidney involvement, suggesting that any bacterial septicemia can potentially result in nephritis.187 Identification of bacteria within renal tissue may be difficult, as has been noted in dogs and swine with renal disease putatively associated with a bacterial etiology.26 Blood cultures are an appropriate consideration if septicemia is suspected. Prior to blood collection, the skin over the venipuncture site is aseptically prepared by thorough cleaning with alcohol and organic iodine (as with surgical preparation). 58,107 The jugular and basilic veins are described as appropriate blood collection sites in septicemic birds. 25,58 Using aseptic techniques, renal biopsy specimens also can be sampled for microbial cultures. The cause of infectious nephritis in birds is not limited to bacteria, and various culture methods and other diagnostic procedures also may be useful for identifying fungal, viral and parasitic organisms.

URINALYSIS

Biochemical and cytological sediment analysis of avian urine has been advocated as potentially useful in diagnosing avian renal disease. 128,166,181,188,228 In birds, hematuria may be noted with renal disease, but should be carefully differentiated from bleeding originating from the gastrointestinal and reproductive tracts. 181 Hemoglobinuria, as noted in Amazona spp. parrots with lead intoxication and in other species with differing disorders, may or may not be related to renal disease. Toxic, neoplastic, bacterial and viral nephropathies may be more frequently seen associated with hematuria in birds. 181 White blood cells were seen in 45% of urine sediment from pigeons with paratyphus, many of which had intersitial nephritis.87 Sediment analysis should be a part of an avian urinalysis and specific cellular urinary components have been discussed. 128,188,228

Several significant factors complicate interpreting avian urinalysis. First, urine is mixed with feces in the cloaca. The one possible exception is the ostrich, which appears to eliminate urinary waste separate from the feces. 168 Second, in many species ureteral urine is refluxed orad

into the lower intestines to the ceca, where water and sometimes electrolyte reabsorption takes place. 252 Additionally, diseases of the lower intestine may alter urine production and composition. Gastrointestinal bleeding, inflammation, normal and abnormal organisms, etc, may end up in a "urinalysis" harvested from a dropping, giving the false impression that red and white blood cells and/or infectious agents, respectively, came from the urinary tract. In short, the "urine" present in a dropping is not the same urine produced from the kidneys. Urinalysis results should be carefully interpreted.

Collection

True urine can be collected in birds only with some difficulty. Once emptied of feces, specially designed cannulas can be inserted into the cloaca for collection of ureteral urine. One group used a Foley catheter to occlude the rectum but not the ureters and successfully collected ureteral urine in chickens.²¹ Small closed-end cannulas constructed from micropipette tips were used to collect ureteral urine from house (Passer domesticus) and song sparrows (Melospiza melodia).38 The opening of the closed-end cannula was placed over the ureteral orifices.³⁸ A similar design was used in house sparrows to make cloacal cannulas from PE-240 tubing with a hole cut near the sealed end.89 The sealed end prevented intestinal fluids from contaminating the urine once the cannula was in place.89 Under local anesthesia, 1.5-ml microcentrifuge tubes were sutured into the cloacas of chickens to allow collection of ureteral urine.205 Cyanoacrylate was used to glue cannulas over the ureteral orifices of chickens.73 Several obvious drawbacks include restraint or sedation of the patient while urine is slowly produced, and the cannulation itself may induce diuresis.249,252 Clearly, there are numerous methods, with varying degrees of difficulty, used to collect ureteral urine.

Casts

Urinary casts represent cellular and/or acellular material sloughed from the inner lining of various renal tubules. This material is generally in the shape (or a "cast") of the tubule from which it originated. Casts are sometimes noted on histologic sections. Protein and cellular casts were histologically noted in an Australian diamond firetail finch (Stagnopleura bella) with Cryptosporidium sp. and multifocal amyloidosis. 19 Albuminous casts in renal tubules of pigeons infected with virulent Trichomonas gallinae were noted. 172 Hyaline casts were identified in kidney sections of birds experimentally infected with infectious bursal disease (Gumboro disease).214 Eosinophilic granular casts have been found within the renal tubules of turkeys afflicted with salt toxicosis.242 Eosinophilic tubular casts, possibly containing myoglobin, in an ostrich with acute muscle necrosis and anuric renal fail-

ure have been reported.187 A rhea with hemoglobinuric nephrosis developed eosinophilic casts in the renal collecting tubules. 16 Both hyaline and granular tubular casts were present in racing pigeons infected with avian paramyxovirus type 1.11 Granular, hyaline and albuminous casts were seen in the renal tubules of chickens experimentally infected with several pathogenic bacteria.219

Identifying casts in urine is reported as highly significant, a sign of renal disease and/or can be a non-specific indicator of tubular renal disease in birds. 128,134 With that stated, the papers cited above describe histological sections with no discussion of casts in the urine. The author disagrees that urinary casts are highly significant or a definite sign of renal disease, as there is little information correlating casts found in a urinalysis with any type of renal disease in birds. However, casts should be noted and may have correlation with some forms of avian renal disease. Epithelial casts were found in 2 out of 35 ostrich urine samples, but no correlation was made with any renal parameters. 168 Epithelial casts were noted in 20% of urine samples from Salmonella typhimurium-infected pigeons.87 Although many birds did have histologically confirmed renal disease, no correlation was made between those pigeons with kidney lesions and those with urinary casts. The large variety of "types" of casts reported also suggests that an inconsistent naming system exists within the current literature.

Urine Chemistries and Electrolytes

Standard mammalian dipsticks may be used, but not all components are applicable to avian urine.166 Chicken urine reportedly contains non-uric acid chromogen.9 Non-protein chromogens are known to interfere with refractometric and chemical measurement of plasma proteins and also may apply to avian urine sampling.81

Few studies even mention test strips used in avian urinalyses. One study evaluated commercial urine dipsticks^a on normal urine of 35 ostriches.¹⁶⁸ Because ostriches can eliminate urinary waste separate from feces, these values may not apply to most other birds. In the study, 31/35 (89%) and 35/35 (100%) of the urine samples were positive for nitrite and protein, respectively. The urine chemistry strips were negative for glucose, urobilinogen, bilirubin and ketones in all ostriches. 168 No association with renal disease was made. Using the dipsticks, nitrite and protein also were positive in 90% (18/20) and 50% (10/20), respectively, of the ureteral urine samples from pigeons with paratyphus.87 The same strips identified blood in all samples, which correlated to red blood cells seen in only 45% of urine sediments.87 If the cells in the urine had been lysed, the strips would be positive and the cytology was negative in this study. Urine strips also may detect undigested hemoglobin found in the

excrement of the bird, especially carnivorous species with short digestion times, and give a positive result. 134 Myoglobinuria also may cause positive reactions and can be distinguished from hemoglobinuria only by spectrophotometry.¹³⁴ Finally, porphyrinuria, as seen with lead-poisoned Amazon parrots (Amazona spp.), may result in red-colored urine visually mimicking hemoglobinuria. 134 Because of the inconsistent results and limited critical studies noted in the literature, difficulty in obtaining ureteral urine and clinical experience, it is the author's opinion that the currently available chemistry strips have limited value in an avian urinalysis.

Urine electrolytes and chemistries can be collected, but there is limited information on their interpretation. It has been suggested that because renal intracellular enzymes are likely voided in the urine, urinary chemistries might be useful in detecting kidney damage.141 Urine sodium and potassium were measured, and insignificantly changed, in house sparrows undergoing trials with the antidiuretic arginine vasotocin.89 One study noted that in normal and dehydrated starlings (Sturnus vulgaris), cloacal urine contained significantly higher concentrations of magnesium, phosphate, potassium and total osmolality than found in ureteral samples.²⁰⁴ This study supports the recommendation that ureteral samples must be collected to obtain a "true" evaluation of avian urine, again making urinary chemistry evaluation impractical in a clinical setting.

One renal enzyme, N-acetyl-ß-D-glucosaminidase (NAG), has been successfully evaluated in the urine of chickens as a marker for kidney damage.74 In mammals and chickens, NAG is a renal tubular enzyme. In humans, urinary NAG has been suggested for use as an early predictor of renal tubular damage and may be a good non-invasive indicator of disease progression. 49 Elevated urinary (ureteral urine), but not plasma, NAG was noted at 40 days of excessive vitamin D₃ supplementation in chickens.⁷⁴ Although the information is limited, further studies may show that NAG, and possibly other urinary enzymes, may become useful as early markers of renal disease in birds.

Osmolality and Specific Gravity

Avian urine is typically isosmotic because the predominant reptilian-type nephrons cannot concentrate urine beyond plasma osmolality.141 In normal birds, urine osmolality can maximally be increased to 2.0 to 2.5 times that of plasma osmolality.^{27,28,40,141} Even this number is high for some species, as emus (Dromiceius novaebollandiae) are reported to have maximal urine to plasma osmotic ratio of only 1.4 to 1.5.216 This is minimal in comparison to some mammals that can concentrate urine osmolality 25 to 30 times that of plasma. 27,28,40

There is limited information on urine specific gravity or osmolality in avian health or disease. The reported average (refractometrically determined) urine specific gravity of ostriches (Strutbio camelus) is 1.02 with a range of 1.01 to 1.05.168 Consistent polyuria and hyposthenuria (60% had specific gravity below 1.007) was noted in Salmonella typhimurium-infected pigeons, many of which had interstitial nephritis.87 In a separate evaluation, urine osmolality significantly increased up to 3 times control levels in postflight and dehydrated pigeons.88 The author has used urine specific gravity diagnostically as discussed below under Water Deprivation Testing.

Urine pH

Urine pH is highly variable in birds. The urine pH may be acid (down to 4.7) in egg-laying female birds during calcium deposition.77 Once the egg is laid or calcium is no longer being deposited, urinary pH may climb to 8.0. Male birds have an approximate urine pH of 6.4. Hypoxia, as noted in diving ducks, may drop urine pH to 4.7.77 Normal ostriches have a urine pH range of 6.1 to 9.1, with a mean of 7.6.168

ELECTROPHORESIS

Plasma Protein Electrophoresis

Properly determined hypoalbuminemia (via plasma electrophoresis) is not reported in confirmed active cases of avian renal disease. However, it is possible that birds may develop low albumin/protein with some kidney disorders. Biochemically determined hypoalbuminemia has been noted in some active avian renal disease cases. 64,65,185

The literature states that as the currently available biochemical tests likely do not accurately report avian albumin levels, serum/plasma protein electrophoresis is necessary to properly quantitate blood proteins and should be performed if hypoalbuminemia is suspected.81,139,142 Decreased albumin and elevated betaglobulins and alpha₂ macroglobulin, as recorded with serum electrophoresis, have been reported with avian nephritis. 47,51 However, there are no controlled studies to support the above statements that correlate protein electrophoresis abnormalities with any renal pathology in birds.

With the above stated, one study showed that an analyzer using the biuret and bromocresol green dye-binding methodologies for total protein and albumin determination, respectively, had good agreement between whole blood and plasma samples.¹¹⁵ On the contrary, there was poor correlation between the results from the studied analyzer and samples evaluated via electrophoresis used at two major reference laboratories. Due to the discrepancies, the authors concluded that neither reference laboratory using electrophoresis served as the "gold standard" for total protein and albumin determination.115

These very limited studies suggest inconsistencies in the "gold standard" method of serum/plasma total protein and albumin determination, and question the true value of these diagnostics in birds with renal disease. Regardless, it is the author's opinion that monitoring serum and/or plasma protein levels has diagnostic value in birds, even if not necessarily used in renal disease cases. The author recommends consistently using one of the common biochemical methods of protein determination and comparing those results to electrophoresis, the goal being to become familiar with test results from one or two diagnostic methods and correlating those results to (histologically) confirmed disease.

Urinary Protein Electrophoresis

In mammals, proteinuria is broken down into preglomerular, glomerular and postglomerular urinary protein loss. Preglomerular proteinuria occurs when large amounts of small molecular weight proteins (immunoglobulin fragments, hemoglobin and myoglobin) that readily pass through normal glomerular walls are lost in the urine.¹³⁷ Glomerular proteinuria occurs when diseased glomerular membranes allow large proteins (albumin, immunoglobulins, some coagulation proteins/ antithrombin III) to pass. 137,245 Postglomerular proteinuria results from normal genital secretions as well as urogenital infections, trauma and neoplasia. 137 Although uncommon in mammals, defects resulting in proximal renal tubular protein resorption result in (postglomerular) tubular proteinuria. 137,245

Avian urine normally contains a large amount of protein (average of 5 mg/ml up to 15 mg/ml), especially when compared to that of mammals (<0.09 mg/ml in dogs and humans).27,111 Amino acids are freely filtered at the glomerulus, but normally are almost completely reabsorbed by the renal tubules in birds. 60 Because uric acid is poorly water soluble, very little avian ureteral urine is required to eliminate this protein waste. Instead, proteinuria is likely necessary to maintain the excreted uric acid-containing spheres in a colloidal suspension, preventing aggregation and renal tubular blockage.28,111 Within the proximal tubule, uric acid is bound to a protein to solubilize the waste product and prevent crystal formation.215 The reflux of urine into the cloaca may be a mechanism to recover some of the urinary protein, as cloacally voided fluid contains very little protein compared to ureteral samples.28

Serum albumin, among other proteins, is found in both the liquid urine and uric acid spheres in chickens.111 In the normal junglefowl (Gallus gallus), the urinary proteins (averaged 2.01 mg/ml urine) identified closely matched the plasma proteins. This led to the conclusion that protein is passed through a glomerular filtration barrier differently than occurs with most mammals.¹¹¹ There are, however, differences in concentrations of plasma and urinary proteins suggesting differential filtration and/or absorption of some proteins by renal tubules.¹¹¹

Pathologic proteinuria is poorly described in birds. In one study, control chickens and those with experimentally induced autoimmune glomerulonephritis produced urinary protein (measured via 3% sulfosalicylic acid with a bovine serum albumin standard) at 5 mg/24 h.21 Test birds developed no abnormal proteinuria, but were considered moderately proteinuric after given IV colloidal carbon (3 to 8 times increase in proteinuria). Colloidal carbon induces proteinuria in other species, but the mechanism is not clear.21 As discussed under Part 1: General Renal Disease Categories, Glomerulopathies, birds may not be capable of developing pathologic proteinuria with glomerular disease as is recognized in mammals. However, it is possible that pathologic proteinuria develops more slowly in birds compared with mammals, and as a result has not been frequently discussed or evaluated in clinical cases.86 If pathologic proteinuria is suspected, urine protein electrophoresis should be used to differentiate protein type and size. 94,245 If performed, it would be beneficial to compare urinary protein levels from a sick patient with samples from a healthy member of the same species. Finally, ureteral urine should be collected to rule out any effects from protein absorption or from other proteins present in the lower intestine. In a normal clinical setting, these collection requirements and limited studies make meaningful urinary protein interpretation in birds impractical.

IMAGING

Radiography

Plain and contrast radiography, nuclear scintigraphy, ultrasound, magnetic resonance imaging and computed tomography can be used to "image" the avian kidneys. 108,134,151,166,181,206 The avian kidney lies in a fossae created by the ventral surface of the synsacrum. 79,152 With bone dorsal and air sacs surrounding ventrally, imaging of the avian renal system is difficult with some techniques. Indirect methods such as positive contrast radiography of the alimentary tract may be helpful in outlining renal masses. 141

A lateral view is the best method to radiographically view the kidneys¹⁴¹ (Fig 16.12). As viewed with a lateral radiograph, the absence of the normal dorsal diverticulum of the abdominal air sac (dorsal to the kidney and ventral to the synsacrum) may indicate renal enlarge-

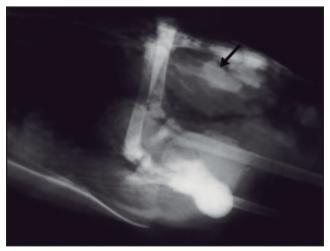

Fig 16.12 | Lateral radiograph of an adult domestic goose with renal fibrosis and mineralization. Note the mineralized kidney tissue (arrow).

ment.^{166,187} Improper positioning can artifactually change the appearance of this air-filled diverticulum.¹⁶⁶ Because the renal silhouettes are superimposed on a lateral view of the abdomen, an oblique view also may be used to distinguish each kidney.⁷⁹ Renal density and gross size changes may indicate renal disease.^{166,181} Radiographically visible renomegaly was noted in a salmon-crested cockatoo with chronic interstitial nephritis and calcification as the result of hypervitaminosis D₃.²¹¹ Nephrocalcinosis was detected radiographically in ostriches and appeared as multiple radio-opacities throughout the renal parenchyma.¹⁶²

Ultrasound

Due to the presence of surrounding air sacs (ventrally) and bone (dorsally and laterally), ultrasonographic imaging of normal avian kidneys is difficult. ¹⁰⁸ In one study of 386 mixed bird species that underwent ultrasonographic evaluation of the urogenital tract, abnormalities such as renal cysts (6), cancer (12) and inflammatory nephromegaly (11) were identified in only 29 patients. The authors concluded that sonographic imaging of the normal kidney was not possible. ¹⁰⁸ Some disease conditions that either obliterate the air sacs or result in fluid accumulation in the coelomic cavity may actually improve renal ultrasonographic imaging. ¹⁵² In these abnormal situations, ultrasonography can serve as a non-invasive and safe means to evaluate coelomic structures such as the kidneys.

Intravenous Excretory Urography

Intravenous excretory urography has been described in birds as a method to gain information on kidney size, shape and function.¹⁴¹ Use of organic iodine compounds given IV in the basilic vein has been reported. The

organic iodine can be visualized radiographically in the heart and pulmonary artery within 10 seconds, and outlining the kidneys and ureters 20 to 50 seconds later. After 2 to 5 minutes, the cloaca will be outlined. This technique should not be used in birds with severe renal compromise.141

It is the author's opinion that intravenous excretory urography may have some limited uses in a clinical setting as demonstrated in the case report below. A watersoluble iodinated contrast agent^b was successfully used to evaluate the ureters post-ureterotomy in a double-yellow headed Amazon parrot (Amazona ochrocephala).56 The agent was dosed at 400 mg/kg and given in the right medial metatarsal vein. Radiographic images were taken at 1, 2, 7 and 10 minutes postinjection. Ureter peristaltic movement and size were successfully evaluated using this technique.56

Renal Scintigraphy

Avian renal scintigraphy has been described. 150 The radioisotopes 99mTc-dimercaptosuccinic acid (99mTc-DMSA) and 99mTc-diethylenetriamine pentaacetic acid (99mTc-DTPA) were used in domestic pigeons. The tested birds were given nephrotoxic doses of gentamicin at 15 mg/kg IM q 12 h for 6 days. The birds were divided into two groups and renal scintigraphy using a mean of 41.8 MBq of intraosseous 99mTc-DMSA or 42.8 MBq of intraosseous 99mTc-DTPA was performed on the last day of gentamicin toxicosis and again 2 days later. Pre and post-gentamicintreated kidneys were biopsied and confirmed normal histology pre-treatment and significant renal damage post-treatment. Uric acid was measured and interestingly did not significantly correlate with renal histology or scintigraphy findings. The authors reported 'decreased renal radiopharmaceutical uptake for 99mTc-DMSA and 99mTc-DTPA indicated nephrotoxicosis'. More specifically, scintigraphy using 99mTc-DTPA correlated well with renal histologic grades. While scintigraphy using 99mTc-DMSA did not correlate well with renal histologic grades it may be used to demarcate neoplasms, cysts and other physical alterations to the renal parenchyma. While renal scintigraphy can be performed at facilities that routinely provide nuclear medicine procedures, obvious drawbacks include cost and the need to confine birds for 12 to 24 hours until the radiopharmaceutical used has degraded.150

WATER DEPRIVATION TESTING

Water deprivation testing is considered when attempting to rule out unknown causes of polyuria/polydipsia (PU/PD) including central and nephrogenic diabetes insipidus and psychogenic polydipsia. There are numerous causes of PU/PD in birds that first must be ruled out

using a complete historical, physical and laboratory evaluation. Some of the many causes of PU/PD in birds include organic (liver, kidney, intestine and cardiac), endocrine (diabetes mellitus) and metabolic (hypercalcemia) diseases.

A water deprivation test is carefully performed using a simple cage. The bird is weighed and blood and urine are collected. Evaluate the packed cell volume (PCV), total solids and osmolality of blood, and specific gravity and osmolality of urine. In one report of an African grey parrot (Psittacus erithacus erithacus) undergoing a water deprivation test, the authors evaluated plasma sodium, potassium and osmolality in addition to the above listed urine parameters.144

Place the avian patient in a cage with no food or water for the duration of the test. Evaluate both blood and urine parameters every 3 to 24 hours for 12 to 48 hours, depending on the species and physical condition of the bird. The reported African grey parrot was evaluated every 24 hours. 144 As a normal response some birds such as European starlings may become distressed within 24 hours of water deprivation, which should be considered when interpreting the results.²⁰⁴ On the other hand, pigeons deprived of water for 36 hours had little change in plasma osmolality, demonstrating the variable responses to dehydration in differing species.88 As a general rule, smaller birds should be evaluated more frequently.

The bird's behavior and laboratory results give a presumptive diagnosis. Birds with psychogenic polydipsia should tolerate this test well and develop more concentrated urine (increased osmolality and specific gravity) and an increase in PCV, total solids and plasma osmolality, all consistent with dehydration. This was the pattern seen in the African grey parrot and subsequent treatment with water restriction proved curative.144 These individual values should all be carefully interpreted as noted in a study of dehydrated starlings where the hematocrit remained unchanged (compared with hydrated birds) and was not a reliable indicator of hydration.204

Birds with central (lack of production of arginine vasotocin [AVT]) or nephrogenic (inadequate response to AVT) diabetes insipidus should have different results than those with psychogenic causes. Birds with diabetes insipidus become dehydrated (as supported by plasma variables) but maintain dilute urine (low specific gravity and osmolality). Normal house sparrows given arginine vasotocin (0.4 ng/kg per minute to 1.6 ng/kg per minute) had a significant drop in urine flow rate (50.2 to 28.9% of normal, respectively) and increased urine osmolality (150.1 to 196% of normal, respectively).89 A similar response would be expected in other normal birds of different species.

A strain of chickens with hereditary diabetes insipidus has been described.³³ These polyuric chickens produced low osmolality urine and maintained high circulating levels of AVT. The vital functions of these chickens became impaired after 48 hours of water deprivation. When given AVT, additional to their high circulating levels, these birds had minimal response. Either the birds had improperly responding kidneys or the AVT was defective.³⁵

In the author's experience with one male canary-winged parakeet (*Brotogeris versicolorus*) with suspected diabetes insipidus, the bird became panicked within 4 hours as he became rapidly dehydrated, but maintained excessive production of dilute urine. The canary-winged parakeet had normal plasma biochemistries, complete blood count, screening radiographs and renal biopsy (light microscopy), and had a history of severe PU/PD since weaning. A diagnosis beyond presumptive diabetes insipidus was not made, since AVT levels were not evaluated.

IDENTIFYING URIC ACID CRYSTALS

Gout results when uric acid precipitates out as a solid, chalky substance in joints (articular) or on tissue surfaces (visceral). Articular gout material may be recovered using fine needle aspiration. Uric acid crystals are easily confirmed using microscopy or the murexide test. Cytologically, "gouty" material typically presents as uric acid crystals surrounded by a pyogranulomatous infiltrate, usually without organisms. The needle-shaped crystals are easy to identify on direct and stained smears. To perform the murexide test, place a small amount of the suspect material on a slide and mix with nitric acid. 141 Use a flame to evaporate and/or dry the mixture. Once cool, add one drop of concentrated ammonia. If urates are present, a mauve color will appear. 141 Due to their watersoluble nature, urates will dissolve in formalin and, therefore, the crystalline form will not be seen on conventionally fixed tissue. However, urates can be seen in alcohol-fixed tissue using Gomori's methenamine silver impregnation technique.141

EVALUATING GLOMERULAR FILTRATION RATE

Glomerular filtration rate has been studied in chickens as a method to evaluate renal function. Glomerular filtration rate is considered the most reliable quantitative index of renal function, and is an important tool for the diagnosis and management of kidney disease of mammals. Most methods of measuring glomerular filtration rate and effective renal plasma flow are difficult and time consuming. As a result, determining glomerular filtration rate in birds is often limited to research situations.

In general, urine flow rate (UFR) is first calculated as the

volume (of ureteral urine) collected per kilogram of body weight per minute. The urine to plasma concentration ratio of a (usually parenterally administered) marker substance such as inulin is multiplied by the urine flow rate. Glomerular filtration rate (milliliters per kilogram body weight per minute) can then be calculated by measuring the clearance of the marker substance.⁷³ The basic formula is as follows:

Glomerular filtration rate =

<u>UFR x urine marker substance concentration (inulin)</u> plasma marker substance concentration (inulin)

The single injection, double isotope method, utilizing ³H-inulin ([methoxy-³H]-inulin) and ¹⁴C-PAH (para-[gly-cyl-1-¹⁴C]-aminohippuric acid), has been shown to be a simple, reliable and rapid method for evaluating renal function in chickens. ¹⁹⁷ If needed, the specific procedures of evaluating glomerular filtration in birds can be reviewed in the literature. ^{73,88,90,131,197,204,249,250}

BIOPSY

When history, physical examination and/or laboratory abnormalities support the presence of renal disease, consider biopsy. Currently, the only way to definitively diagnose avian renal disease and specific pathologic patterns is with a kidney biopsy and histopathologic evaluation. A renal biopsy is most frequently performed during endoscopic examination of the coelomic cavity and, specifically, the kidneys. Before a renal biopsy is performed, the cost:benefit of the surgical procedure versus conservative therapy must be considered, as many birds have compromised health, especially if they have kidney disease.

Several methods of renal biopsy, primarily via endoscopy, and detailed accounts of avian kidney anatomy and physiology have been previously discussed 78,134,165,167,181,227,229,233,234 (Figs 16.13-16.18). For the most part, renal tissues can be stored in 10% formalin for light microscopy. If available, additional tissue may be stored in glutaraldehyde (electron microscopy), culture media (organism recovery) and alcohol (visualizing uric acid crystals), or frozen (PCR studies).

Renal histologic lesions are rarely pathognomonic for a specific disease process. Many different diseases cause similar renal lesions. Additionally, different pathologists may make differing morphologic diagnoses on the same renal tissue. ²³⁹ The author encourages veterinarians to work with a pathologist familiar with normal and abnormal avian histology. Oftentimes, it is the pathologist's interpretation of a renal biopsy combined with the attending veterinarian's case familiarity that enables both parties to make a definitive diagnosis or build a reasonable differential diagnoses list compatible with the kidney lesions noted. This approach has a key role in the

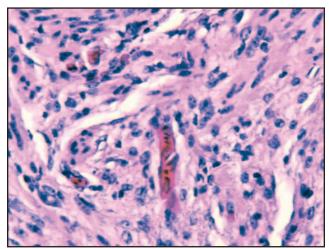

Fig 16.13 | An adult domestic goose with undifferentiated renal sarcoma. The renal architecture is destroyed and has been replaced by neoplastic spindle cells.

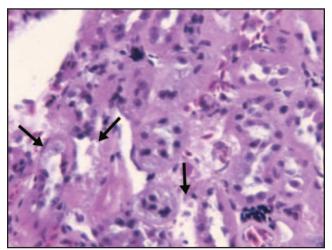

Fig 16.15 | A mitred conure (Aratinga mitrata) with mild nephrosis. Note the cellular disorganization and loss of tubular epithelial cell structure or degeneration (arrows).

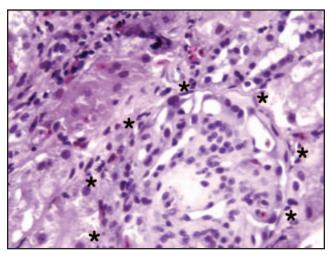

Fig 16.17 | A citron crested cockatoo (Cacatua sulphurea sp.) with membranous glomerulopathy of unknown etiology. Due to the significant mesangial enlargement, the mesangium has been pushed to the periphery of the glomerulus. The round glomerulus is outlined (*).

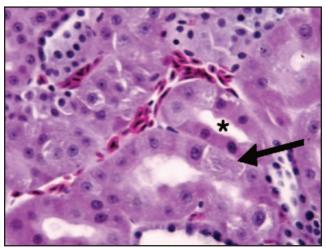

Fig 16.14 | Histologically normal renal tissue from an adult hyacinth macaw (Anodorhynchus hyacinthinus). Note the wellorganized renal tubules, normal tubular lumen size (*) and lack of inflammatory cells. One tubular epithelial cell is undergoing degeneration (arrow), but the cells appear healthy otherwise.

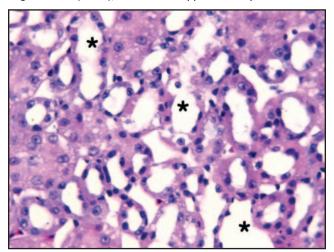

Fig 16.16 | An adult hyacinth macaw (Anodorhynchus hyacinthinus) with mild tubular dilatation 6 weeks post-treatment for histologically suspected bacterial nephritis. Note the multiple dilated renal tubules (*). Although there is no evidence of inflammation, tubular dilatation can be seen with bacterial infections and other diseases, and suggests that complete resolution has not been obtained.

formation of a viable therapeutic plan for the patient.

Treatment

THERAPEUTIC CONSIDERATIONS

Treatment options for renal disorders in birds depend upon the cause and type of kidney disease and secondary complications present. Most renal disease patients are medically managed, as kidney surgery is difficult and often not needed. Tables 16.4 and 16.5 list medications, and their possible indications, commonly used in renal disease patients.

Because of the location within the renal fossae, avian kidneys are difficult to surgically remove. The close associations with the lumbar and sacral plexuses and extensive vascular network surrounding the kidneys lead to the high probability of significant hemorrhage expected during surgery, and possible neurologic damage.79 With that stated, focal therapeutic surgery (including endoscopic biopsy) for superficial renal lesions and the ureters may be useful in some cases. Given the concern of serious hemorrhage, most surgical renal disease cases are managed medically.

A few accounts of therapeutic renal surgery exist. Postrenal failure due to urolithiasis or some other obstruction of the ureters or cloaca may be noted. Cloacaliths and other masses within the cloaca may be easily removed, relieving a potential ureteral obstruction. Wideman and Laverty describe the effects of renal vein and ureter ligation on kidney function in domestic fowl. 250 Except for a small island of tissue adjacent to the testes and cranial renal artery, the cranial, and portions of the middle, renal divisions atrophied significantly without compromising overall kidney function.250 Such a study is worth reviewing if considering renal division ablation or other similar radical procedures. Renal stones were successfully removed via extracorporeal shock wave lithotripsy in a Magellanic penguin (Spheniscus magellanicus). 146 Although multiple anesthetic procedures were required, ureteral stones were successfully removed from a 21-yearold male double-yellow headed Amazon parrot (Amazona ochrocephala).56

The author also has used minor surgery in articular gout cases. In effort to speed the removal of (stabilized) articular gout, make small incisions over the gouty lesions, which are often on the feet. Express the thick material out. Anesthesia is ideal as this can be quite painful. Also, this procedure tends to be bloody, and the feet often require minor bandaging to help prevent continued bleeding and secondary infection.

Another poorly explored area is renal cancer therapy. Clearly, as treatment options advance and are tested in avian species, renal cancer therapy will likely become more prevalent. For example, carboplatin at 5 mg/kg IV q 1 month was used to manage a renal adenocarcinoma (diagnosed at necropsy) in a budgerigar. The bird died approximately 3 months after initiating treatment, but temporarily did show improvement of clinical signs (decreased grip in one foot and lameness changed to almost normal perching, 1 month after starting therapy).147 It was concluded that while carboplatin may be nephrotoxic in birds, this drug could possibly be useful in treating early renal tumors that have not progressed to renal failure.147

As a general note in any bird with organ dysfunction, patients should be monitored with routine physical and laboratory evaluation, especially when taking any medication(s) chronically. The intervals between recheck examinations will vary on the patient's condition and clinician's experience in handling the given case.

DIURESIS AND FLUID THERAPY

As in other animals with renal disease, maintaining hydration is important in birds with most kidney disorders. Acid-base and electrolyte disorders may likely be present in birds with renal disease. At this time, only general statements concerning diuresis and fluid therapy can be made.

Anuric and oliguric patients should be diuresed. Although mannitol and furosemide have been recommended to induce diuresis in birds, these drugs are poorly studied in avian species. 141,181 Mannitol (added to a solution containing inulin and para-amino hippuric acid) was used to induce diuresis in chickens at a dose of 2.5% given at a rate of 0.2 ml/kg per minute.251 Furosemide given IV (1 mg/kg BID) along with SQ saline for 72 hours was used to successfully treat a red-tailed hawk (Buteo jamaicensis) with acute obstructive uric acid nephropathy. 141 Some birds, especially lories, may be sensitive to the effects of furosemide and its use should be judicious.²⁰³ Furosemide also may cause increased urinary excretion of Na+, K+ and Cl^{-,248} If furosemide is used, electrolyte replacement may be needed. Clinically, providing parenteral fluids often induces diuresis in birds, even with most forms of renal disease.

Until acid-base and electrolyte disorders are better evaluated in birds with renal disease, balanced electrolyte solutions should be used to maintain hydration, replace fluid losses and/or induce diuresis as needed. The estimated daily fluid requirement for most birds is 40 to 60 ml/kg per day. 52,223 It has been recommended that 10% of the bird's body weight should be given in fluids when

Table 16.4 | Treatment Guide for Stable Avian Patients with Renal Disease

	Surgery	Fluid Therapy	Antibiotics	Allopurinol	Colchicine	Dietary Modification	Omega-3 Fatty Acids	Parenteral Vitamin A	Low-dose NSAIDs
Nondescript nephritis			+			+	+	+	+
Glomerulopathy							+++		++
Bacterial nephritis			+++				+		
Parasitic nephritis							+		
Nephrosis						++	++	+	
Fatty nephropathy						+++			
Neoplasia	+						++		
Urolithiasis	++					+	++	+	
Amyloidosis					+		+		
Renal fibrosis					+++		+		
Renal (visceral) gout		+++		+++	+++	+	++	+	
Articular gout	+	++		+++	+++	+	++	+	

Note: Most birds with visceral gout are likely in renal failure and usually require immediate medical attention. Fluid therapy, nutritional support and other appropriate supportive care may be required for any bird in poor condition, and treatment choices are based on the bird's health and attending clinician's experience.

NSAIDs = non-steroidal anti-inflammatory drugs

+ = occasionally indicated

++ = occasionally to often indicated

+++ = often indicated

Table 16.5 | Doses and Durations of Drugs Commonly Used in Psittacine Renal Disease Patients (M.S. Echols, unpublished data)^{37,78}

	Dose	Route	Duration	Potential Side Effects
Ceftazidime*	75-200 mg/kg BID-QID	IM, IV	4-6 weeks + for bacterial nephritis	_
Ceftiofur*	100 mg/kg TID	IM	4-6 weeks + for bacterial nephritis	_
Ciprofloxacin*	20-40 mg/kg BID	PO	4-6 weeks + for bacterial nephritis	_
Enrofloxacin*	10-30 mg/kg SID-BID	PO, IM	4-6 weeks + for bacterial nephritis	Muscle/tissue necrosis/irritation upon injection.
Piperacillin*	100-200 mg/kg BID-TID	IM, IV	6 weeks + for bacterial nephritis	_
TMP Sulfa*	16-100 mg/kg BID-TID	PO	6 weeks + for bacterial nephritis. Use lower dose for birds over 300 g.	May cause regurgitation. Use cautiously with dehydrated birds.
Allopurinol	10-30 mg/kg BID	PO	Use until hyperuricemia and/or physical signs of gout normalize. Use higher dose short-term (<4 weeks).	Renal toxicity noted in red-tailed hawks, but not psittacines.
Colchicine	0.04 mg/kg SID-BID	PO	Use until signs of hyperuricemia and/or histologic fibrosis normalize. Can be used with allopurinol and for 6-12 months.	_
Omega(Ω)-3 fatty acids	0.22 ml/kg of a supplement containing <6:1 $(\Omega$ -6: Ω -3 fatty acids)	PO	Use at least until laboratory and/or renal histologic abnormalities normalize. Can be given 6-12+ months.	_
Vitamin A	2000-5000 IU/kg once	IM	Use single dose in conjunction with diet modification. Repeat dose in 3 weeks if needed.	May lead to vitamin A toxicity if used chronically.
Aspirin	0.5-1.0 mg/kg SID-BID	PO	Use until evidence of glomerulopathy is gone or lab abnormalities have normalized. Can be given 6-12 months.	May lead to renal disease if overdosed. Do not use in dehydrated or moderate to severely compromised patients.

^{*}Antibiotic choice should be based on culture and sensitivity (C&S) from histologically confirmed or suspected bacterial nephritis. Otherwise, base antibiotic choice on C&S results from a separate infected lesion, septicemic blood or cloacal cultures.

BID = twice daily

the patient is in renal failure.141 Once a dose has been determined, warmed fluids are given with food (tube/syringe-fed), SQ, IV or IO. The IV and IO routes are most appropriate for critically ill patients.²²³ While appropriate in many cases, subcutaneous fluids are not adequate to rehydrate patients with severe dehydration, shock or hypothermia.²²³ Oral fluids are reserved for stable patients with mild dehydration that have normal gastrointestinal function, and are contraindicated in critically ill birds.112

Fluid therapy for critically ill birds should ideally be tailored to the bird's electrolyte status and/or overall condition and is ultimately decided by the attending clinician. The author typically diureses ill and severely hyperuricemic renal disease patients. While the definition is debatable, the author generally considers severe hyperuricemia to be present when one or more of the following conditions are met in clinically ill non-carnivorous and appropriately fasted carnivorous birds:

1. Uric acid levels exceed 30 mg/dl.

- 2. Uric acid levels are elevated (>10 mg/dl for most species) and rising over a period of several days (even if below 30 mg/dl).
- 3. There is evidence of rapidly progressive articular or visceral gout.

Depending on the patient's condition, the author will typically give 50 to 100 ml/kg of fluid BID via SQ, IV, IO or combination routes. Fluid therapy (combined with other medications if needed) is generally continued until the blood uric acid level drops to either normal or mildly elevated levels (10-20 mg/dl) and the bird is showing signs of improvement (eg, eating, more active). Lower amounts of parenteral fluids are given if overhydration is either suspected or a concern.

ANTIBIOTICS

Antibiotics are indicated in patients with known or suspected bacterial nephritis. Bacterial renal infections in birds may result from an ascending ureteritis, extension from local tissues (eg, peritonitis, oophoritis, salpingitis) and hematogenously. Because of the renal portal system and possible shunting of blood from the intestines directly to the kidneys, alimentary tract organisms may contribute to kidney disease and should be considered when using antimicrobial therapy. Drug choices are based on an isolated renal organism (ie, identified during kidney biopsy sampling) or a suspected infectious agent (blood, ovarian, salpinx, or cloacal/fecal cultures and/or supportive histopathology). Clinical consideration regarding potential antimicrobial-induced toxicities is important.

The distribution, elimination and toxicities of many antimicrobials are poorly defined in most bird species, although an excellent review of antimicrobial use in birds with specific consideration toward the renal system is available. Although mammalian literature warns of potential nephrotoxicity with amphotericin B, cephalosporin, fluoroquinolone, trimethoprim/sulfonamide and tetracycline use, only aminoglycosides have been consistently and definitively associated with renal disease in birds. Those drugs with known potential nephrotoxicity should be cautiously used in birds with renal impairment. Until additional studies are completed in birds, antimicrobials that reach high concentrations in the renal tissue and urine without inducing toxicity should be chosen and cautiously used in kidney disease patients.

The ideal duration recommendable for treating renal infections has not been established in birds. In cats and dogs, greater than 4 to 6 weeks of antimicrobial use is generally recommended for treating bacterial kidney infections. The author's clinical experience with bacterial nephritis suggests that response is best when a mini-

mum of 6 weeks of antibiotic therapy is administered. These suggested guidelines are based on renal histopathologic evaluation supporting the presence of infectious nephritis, post-treatment resolution of clinical pathology abnormalities and improved follow-up kidney biopsy and histopathology in a small number of avian renal disease cases. ^{64,65} There are no controlled studies evaluating antibiotic therapy in active bacterial nephritis cases in birds. ⁶⁴ Additionally, the author will generally treat concurrent colitis (based on culture and sensitivity results of fecal and/or cloacal cultures) for 5 to 7 days, or until signs abate, in renal disease patients.

MANAGING HYPERURICEMIA, RENAL FIBROSIS AND AMYLOIDOSIS

Allopurinol

Allopurinol's main action is to decrease uric acid production. Specifically, allopurinol inhibits xanthine oxidase, which is required to convert hypoxanthine to xanthine and subsequently to uric acid. 35,53,132,195 In chickens, xanthine dehydrogenase, closely related to xanthine oxidase, is the actual enzyme used in this pathway. 35,46,195 Allopurinol has been specifically shown to prevent renal synthesis of urates and allow the excretion of unchanged xanthine. 195 Regardless, both clinical and experimental data show decreased plasma/serum and/or urinary uric acid levels in birds treated with allopurinol. 46,53,68,132,215 Interestingly, allopurinol does not appear to affect pancreatic xanthine dehydrogenase activity, suggesting differing mechanisms of uric acid metabolism in the pancreas and kidney. 132

Specifically in red-tailed hawks (Buteo jamaicensis), allopurinol has been shown to be toxic at 50 mg/kg PO SID with clinical signs of vomiting and laboratory-supported significant hyperuricemia and a renal function disorder. 145 The renal toxicity was even worse and included visceral gout when red-tailed hawks were given 100 mg/kg followed by 50 mg/kg of allopurinol. The toxic signs were attributed to oxypurinol, the active metabolite of allopurinol.145 Allopurinol given at 25 mg/kg SID PO to redtailed hawks was shown to be safe, but had no significant effect on plasma uric acid concentrations. 191c The authors concluded that allopurinol has a very low therapeutic ratio, at best, in red-tailed hawks and that other means of controlling hyperuricemia, such as urate oxidase, in this species should be considered. 191c With the exception of red-tailed hawks, allopurinol use is reported to be nontoxic in birds (in studied chickens), including chicks. 132,181,246 Although the long-term effects are not clear, allopurinol given to chickens increases oxidative activity by lowering plasma uric acid, an important avian antioxidant.215

The author uses allopurinol as a first-line drug to lower

uric acid when fluid therapy and diet modification alone are not sufficient or when hyperuricemia is severe. Clinical experiences suggest that allopurinol is safe to use at published doses in Psittaciformes and Columbiformes, even when used chronically (3-6+ months). Because of the noted toxicities in red-tailed hawks and until further studies are conducted, it is reasonable to assume that allopurinol should be used judiciously, if at all, in birds of prey.

Colchicine

Theoretically, colchicine can reduce serum uric acid levels in birds and be used to control hyperuricemia. In chicken livers, colchicine reversibly inhibits xanthine dehydrogenase (compared to a "pseudo-reversal" with allopurinol). ^{67,68} Colchicine prevents the progression of renal disease in humans with familial Mediterranean fever, a disease of recurring fever often complicated by amyloidosis. ¹⁷⁹ In humans, colchicine is best known for its antigout activity. ¹⁹¹ In small animals, colchicine blocks the synthesis and secretion of serum amyloid A, and decreases the formation and increases the breakdown of collagen. For these reasons, colchicine has been used to treat amyloidosis and hepatic fibrosis, respectively. ¹⁹¹

Clinical use of colchicine suggests possible benefit in reducing hyperuricemia in birds with renal disease. 64,65 The author also has used colchicine to reduce renal (and hepatic) fibrosis in birds, and has had good success based on pre- and post-treatment tissue biopsies (M.S. Echols, unpublished data). As such, the author uses colchicine as a second-line drug to reduce hyperuricemia and a primary medication for histologically confirmed tissue fibrosis. Allopurinol and colchicine are well tolerated when given together in most birds. If diagnosed antemortem, colchicine may be used in birds with amyloidosis. No controlled studies were found using colchicine in birds with renal disease.

Urate Oxidase

Urate oxidase also has been recently discussed as an alternative method to manage hyperuricemia in birds. 1916 At least in humans, urate oxidase is reported to degrade the excess of uric acid to allantoin, which the kidneys can clear more easily than uric acid. Urate oxidase also is very specific for urates and uric acid and does not interfere with the metabolism of purines as does allopurinol. In one study, urate oxidase was given (200 and 600 U/kg and 100 and 200 U/kg IM) to pigeons and red-tailed hawks, respectively. When compared to controls, all dosing regimens caused a significant decrease in plasma uric acid concentrations within 2 days of the first dose. The authors concluded that "urate oxidase is much more effective compared with allopurinol," but this

promising drug needs further evaluation to better understand its use and potential long-term effects. 1916

DIETARY MODIFICATION

As a general note, birds should be fed diets appropriate for their species. Supportive dietary therapy should always be considered in any anorectic patient. As is true with all sick birds, renal disease patients should be weighed routinely at regular intervals and monitored for weight loss.

Protein

The question of dietary protein restriction in the face of renal disease remains controversial. The current human and veterinary literature cites arguments for and against both restriction and supplementation of protein with renal disease patients. 94,95,137,239 The current human literature cites malnutrition (potentially from protein-restricted diets) as the most potent predictor of death in end-stage renal failure. The resultant recommendation is that patients on protein-restricted diets should be well supervised and provided adequate calories. The resultant recommendation are the provided adequate calories.

Although feeding 20% protein to chicks, including young cockatiels, has been recommended as a general level for normal development, excessive protein intake for birds with renal disease has not been determined.²⁰⁷ Feeding diets consisting of 60 and 80% protein (2 separate studies) were required to induce articular gout in genetically predisposed chickens.⁹ In a study using adult cockatiels, birds fed up to 70% protein for 11 months had no evidence of visceral or articular gout or significant renal lesions. This led the authors to the conclusion that, in cockatiels, high dietary protein levels are not associated with kidney dysfunction.¹²³ These experimental diets represent unnaturally high protein levels and do not serve as a realistic evaluation of the effect of diet on renal disease and/or gout in birds.

The management of hypoproteinemia also may be important in birds with renal disease. As mentioned under Part 2: Electrophoresis, Plasma Protein Electrophoresis, the identification of hypoproteinemia and association with renal disease in birds is unclear.

Until further research better defines the role of dietary protein needs in relation to renal disease, avian kidney disease patients should be fed a well-balanced diet appropriate for their respective species. If instituted, birds fed protein-restricted diets should be carefully monitored. No current studies evaluate the effect of low or high-protein diets in birds with naturally occurring renal disease were available at the time of writing. A safe recommendation is that birds with hyperuricemia and/or gout should not consume diets with protein levels greater

than what is considered normal for the given species.

NUTRITIONAL SUPPLEMENTATION

Treatment: Omega-3 Fatty Acids

Omega-3 fatty acids (n-3 FA) have gained popularity for their anti-inflammatory, lipid-stabilizing and antineoplastic effects, renal protective properties and other potential qualities. 12,190 The *n*-3 FA are polyunsaturated and are designated by their first carbon-carbon double bond occurring at the third carbon from the methyl group. 190 The *n*-3 FA are those rich in eicosapentaenoic (EPA), docosahexaenoic (DHA) and/or linolenic acid. 4,31 Flax seed and menhaden (cold-water plankton-feeding fish) oils contain predominately linolenic acid, and EPA and DHA, respectively, and therefore have different n-3 FA compositions.4 DHA and EPA are more readily incorporated into biological tissues, but also carry greater potential to create metabolic oxidative stress than linolenic acid.4 The clinical impact of the differences of the various *n*-3 FA has not been clearly defined.

Studies evaluating *n*-3 FA in mammals serve as the basis for potential treatment value in birds with selected renal disease. At this time, only anecdotal information exists regarding use of *n*-3 FA in birds with renal disease.

In mammals, *n*-3 FA can significantly reduce thromboxane A₂ (TXA) synthesis in platelets and glomerular cells, and increase production of vasodilatory prostaglandins.95 *n*-3 FA partially substitute EPA and DHA for arachidonic acid in membrane phospholipid. 31,104,159 This pathway decreases the release of arachidonic acid and, subsequently, the cyclooxygenase-mediated synthesis of TXA. 31,95,190 In contrast, most animals readily convert omega-6 fatty acids (n-6 FA) to arachidonic acid and, subsequently, eicosanoids (prostaglandins, TXA).³¹ As with arachidonic acid, EPA also serves as a substrate for the formation of vasodilatory prostaglandin/cyclins (PGI/PGE) and their respective products (PGI₂ /PGE₂ and PGI₃ /PGE₃), all of which have similar biologic potency. 95,190 These vasodilatory prostaglandin/cyclins increase renal blood flow and single nephron GFR.31,190

In humans and rats supplemented with *n*-3 FA for at least 4 to 6 weeks, single nephron GFR, plasma flow and renal blood flow increased and/or decreased renal vascular resistance occurred.⁹⁵ In a separate evaluation, dogs on a low-fat diet supplemented with *n*-3 FA had preserved renal function and structure when induced with renal disease.³¹ Another study found that *n*-3 FA supplementation reduced glomerular capillary pressure and prevented deterioration of GFR in dogs with renal disease.³² Compared with controls and thromboxane synthetase inhibitor-treated dogs, beagles supplemented with *n*-3 FA

demonstrated increased renal production and excretion of PGE₂ and PGE₃, which was believed to have stabilized renal tubular lysosomal membranes.⁹⁵ These *n*-3 FA-supplemented dogs had decreased gentamicin-induced proximal tubular necrosis when compared to controls.⁹⁵

Specific toxicities associated with *n*-3 FA supplementation are poorly described, but some potential adverse effects may occur. Chickens fed diets high in *n*-3 FA had reduced plasma and tissue vitamin E (the body's primary antioxidant) and plasma carotenoid levels due to lipid peroxidation.^{4,5,230} Therefore, supplementing the diet with *n*-3 FA increases the requirements for dietary vitamin E.^{4,45} As supported by clinical investigations, vitamin E supplementation should be considered with use of *n*-3 FA or any other polyunsaturated fatty acids.^{182,230} Specifically, 160 mg/kg of vitamin E (dl-α-tocopherol acetate) was shown to prevent loss of α-tocopherol in tissues, and normalize or increase resistance to lipid peroxidation in chickens fed a commercial diet supplemented with 3% tuna oil (*n*-3 FA).²³⁰

Other potential side effects may be noted with n-3 FA supplementation in birds. Menhaden oil supplementation in laying chickens has been shown to contribute to hepatic lipidosis, likely via enhancing the lipogenic activity (along with estradiol) of the liver.240 This study cautions the use of *n*-3 FA in reproductively active hens. In another study, chickens fed diets high in n-3 FA had no alteration in primary or secondary humoral response, but experienced a 50% reduction in antibody-dependent cell cytotoxicity (ADCC).80 The concern presented therein was that reduction in ADCC-related immune functions might increase a patient's susceptibility to certain disease (Marek's).80 The *n*-3 FA supplementation also may affect the ability of antigen-presenting cells to present antigen, again suggesting the potential for immune system alteration. 103 An increased incidence of infectious disease in birds has not definitively been associated with *n*-3 FA supplementation.

Although specific doses have not been established, some believe that the appropriate *n*-6 to *n*-3 FA ratio is more important to inhibiting eicosanoid synthesis from arachidonic acid than is the absolute amount of *n*-3 FA.⁹⁵ A dietary *n*-6 FA:*n*-3 FA ranging from 5:1 to 15:1 has been proposed as desirable for dogs and cats with renal disease.³¹ Using the above dietary guideline, 2 to 4 weeks are required to see any initial effects of the dietary change in dogs and cats.³¹ One study in chickens showed that maximal *n*-3 FA tissue (egg yolk) levels were obtained after 3 to 4 weeks of supplementation.²⁴⁰ Long-term supplementation (3 to 6 months or more) is likely appropriate if *n*-3 FA are to be used.

The author has successfully used supplements containing

n-6 FA:n-3 FA of 4-5:1 to 1:3 combined with low-dose aspirin (0.5-1.0 mg/kg PO q 12 h) to manage histologically confirmed glomerulopathies in avian patients (M.S. Echols, unpublished data). Success was gauged on normalized hyperuricemia (4/4), improved clinical appearance (3/4) and repeat renal biopsy showing normal glomerular light microscopic histology (1/1) in an African grey parrot (Psittacus erithacus erithacus), citron-crested cockatoo (Cacatua sulphurea citrinocristata), red-lored Amazon parrot (Amazona autumnalis) and a ring-neck dove (Streptopelia risoria) (M.S. Echols, unpublished data). The author also has used a supplement^c containing *n*-6 FA:*n*-3 FA of 1:3 (0.22 ml/kg body weight, PO, SID) alone to manage various forms of renal disease in mixed avian species with no recognized adverse side effects. Unfortunately, no clinical trials using fatty acids in avian renal disease were found, only anecdotal reports such as noted here.

Vitamin A

Parenteral vitamin A has been recommended in birds with renal disease.141 Hypovitaminosis A is a reported cause of renal failure and results from metaplasia of the ureters leading to hyperkeratinization, decreased mucin production and impaction. 116,214 Vitamin A deficiency is discussed in more detail in Chapter 4, Nutritional Considerations. In birds with suspected hypovitaminosis A and renal disease, appropriate diet modification and short-term parenteral vitamin A are logical components of therapy. In such situations, the author gives a single IM vitamin A injection at the beginning of the therapy and recommends correcting the patient's diet to improve long-term nutritional status. The diet must be evaluated and the potential of hypervitaminosis A must be ruled out prior to parenteral vitamin A administration. See Chapter 4, Nutritional Considerations: Section II, Nutritional Disorders for more about hypervitaminosis A.

NON-STEROIDAL **ANTI-INFLAMMATORY DRUGS**

Non-steroidal anti-inflammatory drugs (NSAIDs) are frequently discussed for use in human and animal renal disease patients. 92,94,95,135,179 In general, NSAIDs such as aspirin and ibuprofen are non-specific cyclooxygenase inhibitors. Low doses of aspirin may actually inhibit platelet cyclooxygenase production, but allow beneficial (vasodilatory) prostacyclin formation and may be safe.94 Consequently, low-dose aspirin therapy has been suggested to reduce platelet aggregation and subsequent thromboembolism, and to minimize glomerular inflammation for mammalian patients with some glomerulopathies. 94,137 More specific NSAIDs such as thromboxane synthetase inhibitors have been shown to attenuate

renal dysfunction/damage as noted by one or more of the following: decreased proteinuria, enzymuria and tubular necrosis, and preserved renal blood flow and GFR in various animals with a variety of renal diseases. 92,94,95,135 Unfortunately, the beneficial effects of lowdose or specific NSAID therapy have not been studied in birds with renal disease.

Although there are limited avian studies, most NSAIDs are eliminated by renal clearance and should be used with caution, as they have been associated with a variety of renal lesions in birds and mammals. 6,120,137,179,196 Flunixin meglumine^d-induced glomerular lesions in bobwhite quail (Colinus virginianus) that increased in severity proportionally with the dose. In this short study, no biochemical or electrolyte parameters were altered, but uric acid was not measured. 120 Aspirin has been associated with significant inhibition of prostaglandin synthesis (specifically prostaglandin $F_{2\alpha}$) in Japanese quail.¹⁶⁴ In this same experiment, aspirin was shown to induce liver enlargement resulting from hepatic lipid accumulation in n-6 FA-deficient Japanese quail. 164 Acetylsalicylic acid (aspirin) injected IV into Pekin ducks induced temporary diuresis lasting 30 minutes, which is in contrast to the antidiuretic effect seen in mammals, and had no effect on GFR or peripheral blood pressure. 97 Several Gyps spp. of vultures have died with renal failure and gout as a direct result of consuming diclofenac-treated livestock.175b The veterinary use of diclofenac has been specifically implicated in the decline of the critically endangered Oriental white-backed vulture (Gyps bengalensis) in Pakistan. 175b These scattered studies serve only to point out potential varied effects of NSAIDs in

Even with the noted toxicities and lack of therapeutic studies in birds, the author feels that low-dose aspirin, and possibly other NSAIDs, use can be beneficial in avian kidney disease patients. In the author's experience, low-dose aspirin (0.5-1.0 mg/kg PO q 12 h) combined with n-3 FA supplementation is safe and may be effective at reducing the severity of some forms of avian renal disease, especially glomerular disorders (M.S. Echols, unpublished data). Aspirin (and *n*-3 FA) therapy can be used chronically, and the author discontinues use once evidence of renal disease is gone or the disorder is satisfactorily managed.

TREATMENT SUMMARY

Treatments of avian renal disease should be individualized according to the patient's needs, accurate renal histologic diagnosis (if available), concurrent disorders and client considerations. Identified parasites are treated appropriately. If ova are identified in the urine, consider whether or not the eggs were actually released in the

intestines. Treatment of bacterial nephritis with appropriate antibiotics should be based, in part, on culture and sensitivity results when available. Otherwise, suspected bacterial-induced nephritis should be treated with broadspectrum bacteriocidal antibiotics that reach high kidney concentrations and which are non-nephrotoxic. Antibacterials also should be considered when concurrent colitis is present. Removing known nephrotoxins and addressing secondary complications may best manage nephrosis. Such secondary complication of any renal disease may include dehydration, hyperuricemia, fibrosis, infectious diseases and anorexia. Dietary-induced renal diseases can be managed with diet change or supplementation, depending on the etiology. Antineoplastic treatment of certain avian renal tumors may be indicated and should be considered. Specifically identifying and managing underlying diseases that may be concurrently present may best control glomerulopathies. Confirmed glomerular disorders in birds without an obvious underlying disease may be managed in some cases with low-dose aspirin and N-3 FA supplementation. Nutritional management such as weight loss, providing a balanced diet and vitamin A supplementation also may be indicated.

Table 16.6 represents a quick treatment summary of some of the more common renal disease classifications.

Table 16.6 | Avian Renal Disease Treatment Summary

- **Nephrosis:** Parenteral vitamin A. Remove exposure to toxins if known. Consider *n*-3 FA supplementation.
- Glomerulopathy: If identifiable, remove/control any source of infection/inflammation. Give n-3 FA and low-dose aspirin until all signs of renal disease (hyperuricemia, histologic changes, etc) are gone. n-3 FA can be given chronically if needed.
- Bacterial Nephritis: Antibiotics for a minimum of 4 to 6 weeks.
- "Diet-induced Renal Disease of Color Variety
 Psittacine Birds": Discontinue pellets and change diet over
 to whole grains, seeds, fruits and vegetables as is appropri ate for the species. If after 3 to 6 months all signs of renal
 disease are gone, pellets (<50% of total diet) can be cau tiously added to the diet.</p>
- Renal Fibrosis: Use colchicine until histologic fibrosis resolves. Otherwise, use colchicine for 6 to 12 months or until laboratory abnormalities normalize. The n-3 FA also may be beneficial.
- Articular Gout: Use colchicine and allopurinol together
 until all signs of gout and hyperuricemia have resolved.
 Consider diagnosing the cause of probable underlying
 renal disease and manage appropriately. Give vitamin A if
 hypovitaminosis A is suspected. Articular gout lesions also
 may be surgically opened and expressed to speed removal
 of uric acid crystal accumulation. n-3 FA may be beneficial.
 Use aggressive fluid therapy if articular or visceral gout is
 accumulating rapidly. See Chapter 4, Nutritional
 Considerations: Section 2, Nutritional Disorders.

Articular gout, although not a renal disease, also is included. With the possible exception of "diet-induced renal disease of color variety psittacine birds," the patient's diet should be modified as is appropriate for that avian species. Secondary infections, dehydration, unacceptable weight loss, etc, should be managed as needed. Combination therapy should be considered when two or more histologic renal lesions are present.

Prognosis

The World Health Organization classification of renal disease is based on distinct glomerular pathological findings and is used for prognosis, treatment and outcome. 109 Presently, no such classification system exists in avian medicine. In fact, there are limited studies that estimate the outcome of selected avian renal disorders. One such review noted that most birds live less than 3 months following a diagnosis of a renal neoplasm. 79 This may seem to offer a poor prognosis, but represents only one form of renal disease that is usually diagnosed late and with which there are few treatment options. Based on the author's experience, several forms of renal disease can be successfully managed and some resolved, giving a good prognosis for long-term health to the individual patient.

Clinicians are encouraged to thoroughly evaluate each avian renal disease patient individually from diagnosis through to management or completion of treatment. Consider renal biopsy as a viable tool for diagnosing and managing disease. Dr. Robert Schmidt states, "The problem is that clinical lab tests may indicate renal disease in birds, but several kidney disorders cause similar (lab) abnormalities. If you want a definitive diagnosis, biopsy the kidney" (R. Schmidt, personal communication, 2003). Treatment completion may have to be defined, in some cases, as return to normal renal histology by follow-up biopsy. Until renal diseases of birds are better understood, classified and treated, the short- and longterm prognoses can be estimated based only on the severity of kidney lesions at that time and secondary disorders of the patient.

Evaluating and Treating the

Nervous System

SIMON R. PLATT, BVM&S, MRCVS, Dipl ACVIM (Neurology), Dipl ECVN, RCVS Specialist in Veterinary Neurology

The nervous system plays a role in nearly all body processes. Disease syndromes may affect the central nervous system (CNS), which includes the brain and spinal cord, and the peripheral nervous system, which includes cranial nerves, spinal cord nerve roots, spinal nerves, peripheral nerve branches and the neuromuscular junction. Evaluation of the nervous system of birds parallels that of mammals, with modifications specific to avian anatomy, behavior and physiology. An understanding of basic avian neuroanatomy is necessary to evaluate abnormal function of the nervous system. ^{15,16,62,87}

Suspicion of neurologic dysfunction arises from the history and physical examination. The signalment, presenting chief complaint, time course of clinical signs, and history may suggest the type of disease process or speciesspecific disorder. A complete neurologic examination is necessary to localize the anatomic distribution, to determine the severity of the disease process, and to assess the prognosis for patient recovery. A minimum database consisting of a complete blood count (CBC), serum or plasma biochemical analysis, and cytologic evaluation of choanal and cloacal swab samples is used to evaluate the contribution of other body systems to the observed clinical signs and physical abnormalities. If neuromuscular disease is suspected, electrophysiological tests are indicated, including electromyography and nerve conduction velocities, and these are becoming more commonly performed in birds. In recent years with the advancement of imaging technology and the improved availability for veterinary patients, scintigraphy, computed tomography and magnetic resonance imaging have been valuable diagnostic commodities in furthering our understanding of avian CNS disease. Only when a disease location and a pathologic process have been identified can appropriate treatment and prognosis be provided.

Anatomy and Physiology

Complete reviews of avian neuroanatomy are documented in other texts. 15,62,85,87 For a detailed description of the functional organization of the avian spinal cord, the reader is referred to an avian physiology text.83 The general organization of the avian spinal cord resembles that of all other vertebrates. There are however, some specializations, which birds largely share with the phylogenetically related class of reptiles. Compared to the mammalian cord, the most outstanding deviations are the lack of a cauda equina and a filum terminale and the occurrence of a sinus rhomboidalis or lumbosacralis.83 At the microscopic level there are some significant differences in the organization of cell groups and pathways. Birds differ from most other vertebrates in their locomotion due to bipedal walk and flight. It has to be kept in mind that specializations in the spinal cord may result from adaptations from this peculiar kind of locomotion.

Control of Eye and Head Movements

A sitting bird is able to survey a large part of its surroundings using both head and eye movements. Several types of eye movements can be distinguished such as saccades (fast flicks elicited by a sudden stimulus) and smooth pursuit (following a moving target).³³ Six muscles are responsible for all movements of the eye. Branches of the oculomotor, trochlear and abducens nerves innervate these extrinsic eye muscles. The two muscles that rotate the eye dorsally are innervated by contralateral centers, with the other muscles innervated by ipsilateral cell groups. These are stimulated by the vestibular centers.³⁷

Control of Jaw and Tongue Movements

The jaw muscles have a visceral origin; therefore, the nerves innervating these muscles and the corresponding motor nuclei are considered visceromotor elements.³³ A complication in parrots is that they possess a so-called kinetic skull. This means that not only the lower jaw but also the upper jaw moves to open the beak.³³ Movement of the beak is achieved by four groups of muscles: two groups of beak openers and two groups of beak closers.

Movements of the tongue are caused by two groups of muscles. The extrinsic muscles are part of the visceral musculature, similar to the jaw muscles, and the intrinsic muscles have a somatic origin innervated by the hypoglossal nerve. Because the jaws and tongue move in close harmony during feeding and drinking, a premotor system is needed to coordinate the activity of the tongue and jaw motor centers.³³

Control of Locomotion

The reticular formation in the brain stem also contains

premotor neurons of the motor systems of the spinal cord, thus controlling flying and walking. The final affectors of wing and leg movement are the lower motor neurons of the brachial and lumbar plexuses, respectively. In-depth review of this area is covered in an avian physiology text.^{15,35}

Control of Vocalization and Respiration

Birds use their syrinx, an organ at the transition of the trachea and bronchi, to produce sounds. Vocalization depends upon the control of a few small syringeal muscles and the precise regulation of the stream of (expiratory) air passing through the trachea. This requires a close coordination of the motor centers of the syringeal and respiratory muscles. The caudal part of the dorsal hypoglossal motor nucleus innervates the syringeal muscles, whereas the motor cells of the respiratory muscles are part of the motor system of the spinal cord. However, several cell groups in the cranial and caudal brainstem have a role in the control of respiration. In songbirds, these centers are all under direct telencephalic (cerebral) control. ¹²⁰ See Chapter 19, Endocrine Considerations.

Control of Coordination

Birds possess a well-developed cerebellum but, as in mammals, its precise role in the control of motor activity is not well understood. However, there is little doubt that the ease and precision of motor performance depend upon an intact cerebellum. The axons of the Purkinje cells form the output of the cerebellar cortex; the central cerebellar nuclei and some vestibular nuclei are the targets of these fibers.³³ The Purkinje cells have an inhibitory effect on the activity of the central nuclei.

Neurological Examination and Lesion Localization

A neurological examination is easily integrated into a routine physical examination. The objectives of the neurological examination are to confirm if there is a neurological abnormality and to specifically localize the abnormality within the nervous system. In conjunction with the history, signalment, presenting complaint and the physical examination, the neurological lesion localization is a piece of a jigsaw, essential to creating a list of differential diagnoses for the disease. However, caution must be used, as some manipulations necessary for the neurological examination could exacerbate problems such as spinal cord disease. 80

OBSERVATION

Observation of the bird is essential, as it allows evalua-

tion of the bird's mentation (level and content of consciousness), posture, attitude and gait. Changes in mentation are revealed by a history of personality change, change in awareness of surroundings and inappropriate behavioral responses. ²⁶ Consciousness is a function of the brainstem (responsible for arousal) and the cerebral cortex (responsible for content and regulation). ^{26,40,101,117,119}

PALPATION

The bird's musculoskeletal system should be palpated for asymmetry, masses, tenderness, contour and tone. A mass effect, tenderness or contour change requires further investigation. The vertebral column should be palpated for deviations and pain, being cautious not to apply too much pressure if there is suspicion of an instability. Unilateral muscle mass loss or atrophy may indicate disuse if it is chronic, or a neurogenic loss if it is acute (within 7 to 10 days).²⁶

CRANIAL NERVES (CNs)

Several differences exist between the neuroanatomy of avian and mammalian species.^{15,26} Cranial nerves have specific functions and evaluation of these functions can help to precisely locate a neurological lesion due to their well-documented anatomy. The general functions and specific tests are summarized in Table 17.1.

Simplistically, cranial nerve dysfunction may indicate a CNS lesion (brainstem disease) or a peripheral lesion (affecting the cranial nerves after they have exited the brainstem and course through the skull). Evaluation of the cranial nerves should follow observation and palpation, with particular attention paid to normal functions of eye movement, head movement, blinking, jaw and tongue movement, and general symmetry of the head.

Initially an ophthalmic exam should be performed, which will assist with the evaluation of the optic (CN II), oculomotor (CN III), trochlear (CN IV), abducens (CN VI), and trigeminal (CN V) nerves. ^{15,16,62} The following tests are essential to the evaluation of cranial nerve function.

The Menace Response

How to Perform

Obscure the vision in one eye and make a slow, threatening hand gesture toward the other eye (Fig 17.1).

How to Interpret

This is a learned response, not a reflex, to a perceived threat, which evaluates CNs II and V (responsible for innervation of the *orbicularis oculi* muscle, which closes the eyelids), as well as the central visual pathways and the cerebellum. 62.87 Birds that are stoic or excited may not show a menace response even though nerve function is

Table 17.1 | Cranial Nerves: Function and Applicable Tests

Cranial Nerve	Nerve Function	Applicable Tests
I. Olfactory	Smell	None applicable
II. Optic	Vision	i. Menace response ii. Pupillary light reflex
III. Oculomotor	Extrinsic and intrin- sic ocular muscles/ upper eyelid muscle	i. Eyeball position ii. Menace response iii. Pupillary light reflex
IV. Trochlear	Extrinsic ocular muscles	i. Eyeball position
V. Trigeminal	Facial and beak sensation/beak movement	i. Palpebral reflex ii. Jaw palpation
VI. Abducens	Extrinsic ocular muscles and third eyelid muscle	i. Eyeball position
VII. Facial	Muscles of facial expression	None applicable
VIII. Vestibulocochlear	Hearing and balance	i. Startle ii. Oculocephalic reflexes
IX. Glossopharyngeal	Muscles of pharynx, larynx, crop and syrinx	i. Gag reflex
X. Vagus	Muscles of larynx, pharynx, esophagus and crop	i. Gag reflex
XI. Accessory	Superficial neck muscles	None applicable
VII. Hypoglossal	Muscles of tongue, trachea and syrinx	i. Tongue grab/ inspection

Fig 17.1 | The menace reaction is performed by making a threatening gesture with fingers or hand toward one eye and watching for a blinking action.

intact. Normal function is demonstrated by a blink. To localize the lesion, other cranial nerve tests would be required.

The Pupillary Light Reflex

How to Perform

Shine a bright light in each eye to evaluate the response of the pupil (Fig 17.2).

How to Interpret

This is a reflex. Light is sensed by CN II; parasympathetic

Fig 17.2 | The pupillary light response is performed by shining a light source into one eye at a time and monitoring the response of the pupil.

fibers of CN III cause contraction of the iris muscle in normal birds with direct stimulation. There is no consensual response in birds due to the 100% decussation of the optic nerves at the optic chiasm. ²⁶ However, some raptors have an incomplete bony septum between the globes and may respond to light reaching the contralateral retina, mimicking a consensual response. ⁸² The response may not be as marked as that seen in mammals, as birds have striated muscle in the iris, giving them some voluntary control over pupil size independent of light intensity. This reflex is best evaluated as soon as possible during the examination, as sympathetic tone in restrained birds may override constriction.

Evaluation of Strabismus

How to Perform

Observe the bird's head in a normal position for a deviation of one or both globes in the orbit(s).

How to Interpret

Cranial nerves III, IV and VI aid vision by maintaining the globe in a central position. Deviation of the globe from its central axis indicates dysfunction in one or more of these nerves: ventrolateral — CN III, dorsolateral — CN IV, and medial — CN VI. In contrast to mammals, the third eyelid in birds has striated muscle fibers, innervated by CN VI, that initiate movement of the nictitans across the cornea. ^{20,59,62,82,87} Prolapse of the third eyelid in birds does not directly indicate loss of sympathetic innervation, as found in Horner's syndrome in mammals.

The Palpebral Reflex

How to Perform

Touch the medial canthus of the normal eyelid and watch the response (Fig 17.3).

Fig 17.3 | The palpebral reflex is performed by touching the medial canthus of the palpebral fissures and watching for a blink in response.

Fig 17.4 | A cockatiel (*Nymphicus hollandicus*) with eyelid paresis from infraorbital sinus infection demonstrates a cranial nerve V lesion.

How to Interpret

The normal eyelid should close. Cranial nerve V (trigeminal nerve) is responsible for facial sensation, whereas the motor response to facial sensory stimulation is generally provided by the facial nerve (CN VII). The eyelids are innervated by CN V in birds. ^{39,62,87} Eyelid sensation is provided by the ophthalmic branch (upper lid) and the maxillary branch (both lids) of CN V. Eyelid closure is provided by the mandibular branch (*orbicularis oculi* muscle) of CN V that, when damaged, may present as eyelid paresis (Fig 17.4).

Evaluation of Jaw/Beak Tone

How to Perform

Observe the bird for a dropped lower beak and/or an inability to eat with the beak. Assess the strength of the beak safely by manually opening the beak and evaluating the resistance to opening (Figs 17.5a,b).

How to Interpret

The mandibular branch of CN V provides motor func-

Fig 17.5a | The beak is assessed for strength and movement.

Fig 17.5b | The movement and symmetry of the tongue can be assessed by forcing open the beak or using a speculum.

tion to the jaw^{39,87} A dropped lower beak or the inability to chew indicates damage to CN V. Cranial nerve VII contributes to prehension by partial innervation of the muscles that open the jaw.

The Oculocephalic Reflex/Interpretation of Nystagmus

How to Perform

Move the head from side to side in a horizontal plane and observe the resulting movement of the eyes (Fig 17.6).

How to Interpret

In normal birds, a physiological nystagmus will be induced, with the fast phase in the direction of head movement. This reflex tests the integrity of CN VIII (vestibulocochlear nerve), which is the sensory arm of this reflex, and CNs III, IV and VI, which are responsible for the motor movement of the eyes. Clinical signs of peripheral vestibular disease are manifest after damage to the inner ear or vestibular branch of CN VIII, which effectively gives unbalanced input to the intact central vestibular system.²⁶ In the absence of head motion, spontaneous horizontal nystagmus is consistent with CN VIII damage, with the fast component away from the side of the lesion. Unilateral peripheral disease may cause a head tilt with circling toward the side of the lesion.

POSTURAL REACTIONS

The postural reactions are complex, requiring intact sensory and motor pathways throughout the nervous system, as well as unimpaired processing and integration in the brain. The complexity of the postural reactions allows detection of minor deficits in any key component of the pathway. Postural deficits are seen caudal to or at the level of the lesion. Additional testing must be performed to use the postural deficit to help localize the lesion within the pathway of the deficit.

How to Perform

A wing or leg is placed in an abnormal position and a correcting response by the bird is observed. Not all standard mammalian postural reactions can be done due to the modifications of the forelimbs in birds. However, knuckling the toes over while supporting the bird can be done to evaluate how long it takes for the bird to correct. Placing the bird's foot on its dorsal surface against a perch may be a more practical way to test proprioception in the limbs. Alternatively, a piece of paper may be placed under each foot and slowly moved sideways to see if the bird returns its foot to the standing position. Placing reactions of the wings are not evaluated routinely in birds. Placing reactions in the rear limbs may be helpful. Visual placing may be evaluated crudely by offering a perch for the patient to step onto (Fig 17.7). Tactile placing may be evaluated in birds such as ratites and raptors that allow hooding. A perch may be touched to the dorsum of the foot to initiate a step-up.

How to Interpret

Conscious proprioception is the patient's awareness of limb position and movement without visual information. The sensory branch of proprioception is carried from the skin, muscle and joints of the leg, through the spinal cord and brainstem to the sensory motor cortex where the brain responds by sending messages back to the lower motor neuron for motor function, resulting in a rapid correcting foot placement.²⁶ Ascending sensory pathways are located in the outermost regions of the spinal cord and are very sensitive to compression. 40,87 With minor spinal cord injury, proprioceptive deficits may be present because of disrupted sensory pathways, while motor function persists because the deeper motor tracts are unaffected. Both visual and tactile placing reactions require an intact motor cortex and intact motor pathways to the involved limb. A cortical lesion may

Fig 17.6 | By moving the head from side to side, the movements of the eyes can be evaluated for physiological nystagmus.

Table 17.2 | Clinical Signs Associated with Upper Motor Neuron (UMN) and Lower Motor Neuron (LMN) Diseases

Clinical Function	UMN Disease	LMN Disease
Motor function	Paresis or paralysis	Paresis or paralysis
Muscle tone	Normal to increased	Often reduced
Spinal reflexes	Normal to decreased	Decreased to absent
Muscle mass	Normal to decreased (disuse atrophy)	Dramatically decreased after 5-7 days (neurogenic atrophy)
Conscious proprioception	Often reduced to absent	Often reduced to absent

produce deficits in the contralateral limb, whereas a lower lesion produces deficits in the ipsilateral limb.

SPINAL REFLEXES

Completion of a reflex requires an intact sensory nerve that provides transmission to the spinal cord and an intact motor nerve that elicits function from the innervated muscle. The reflex arc itself does not involve the brain or the remainder of the spinal cord. Lesions in the motor arm of the reflex arc, termed lower motor neuron (LMN), may cause a decreased or absent reflex (hyporeflexia or areflexia). An exaggerated response (hyperreflexia) results from an interruption in proximal motor pathways that modulate the reflex, termed upper motor neuron (UMN). Lower motor neuron signs indicate damage to one or more components of the reflex arc. Upper motor neuron signs indicate damage anywhere between the reflex arc and the brain (Table 17.2). 39,62,87

The Vent Sphincter Reflex

How to Perform

Pinch or prick the vent and watch for a wink-like contraction of the external sphincter muscles and a tail bob.

Fig 17.7 | Bringing the bird to a perch will assess the ability to place the limbs properly; this is one method of assessing proprioception. The bird also can be visually restricted using hooding.

Fig 17.8 | The pedal withdrawal can be evaluated by applying a pinching stimulus to the digits and watching for flexion and withdrawal of the joints and limb, respectively.

How to Interpret

This reflex reveals information regarding the pudendal plexus and caudal segments of the spinal cord. A flaccid, unresponsive vent and overdistended cloaca that is easily expressed indicate LMN damage to the pudendal nerve or its spinal roots. A hypertonic, hyperresponsive vent indicates UMN damage at any point cranial to the pudendal plexus.

The Pedal Flexor Reflex

How to Perform

Apply a pinch stimulus to the skin of each foot and evaluate the response of the ipsilateral and contralateral limb (Fig 17.8).

How to Interpret

This is a withdrawal reflex in which stimulation of sensory receptors in the feet elicits contraction of flexor muscle groups in the leg. Presence of a withdrawal

Fig 17.9 | With the limb allowed free movement, the patella reflex can be performed by applying a stretch stimulus to the patellar tendon.

Fig 17.10 | The wing withdrawal can be assessed by stretching each wing out and applying gentle pinching stimulus, watching a complete flexion and withdrawal.

reflex requires an intact ischiatic nerve (sensory and motor) and an intact spinal segment at the sacral plexus, but does not require transmission along the spinal cord to the brain. Absence of the withdrawal reflex in the leg denotes extensive lower motor neuron damage involving the sacral plexus or the ischiatic nerve. A space-occupying mass within the kidney or pelvic canal, such as a renal tumor or an egg, may impinge upon the lumbosacral plexus and its nerve, causing a hyporeflexic or areflexic withdrawal in the legs.¹⁵

The Patellar Reflex

How to Perform

A tap stimulus should be applied to the straight patellar tendon and the response of the limb should be evaluated (Fig 17.9). Certain birds, such as ostriches,²⁶ do not have a patella; in these species, the homologous straight quadriceps tendon is stimulated. Plexor size must be adapted to patient size for improved accuracy. Because of interference from the inguinal web, this reflex may be difficult to elicit in birds.²⁶

How to Interpret

This is a myotatic (stretch) reflex that effectively stretches the *femorotibialis* muscle.⁸⁷ This stretch stimulates the femoral nerve (lumbosacral plexus), which generates muscular contraction to extend the stifle. Upper motor neuron lesions cause hyperreflexia and should be accompanied by weakness.²⁶ Disease in the lumbosacral plexus or peripheral muscle or nerve (LMN) causes hyporeflexia.

The Wing Withdrawal Reflex

How to Perform

A pinch stimulus to the major digit at the leading edge of the primary flight feathers generates flexion of the wing in the normal bird (Fig 17.10).

How to Interpret

This reflex tests the integrity of the reflex arc to the brachial plexus spinal segment. Absence of the wing withdrawal reflex in a wing indicates damage to the brachial plexus or its nerves. A positive crossed extensor reflex of a wing denotes damage cranial to the brachial plexus within the cervical spinal cord or the brain stem.

CUTANEOUS SENSATION AND PAIN

Cutaneous sensation testing provides information regarding the location and severity of a spinal cord or plexus lesion.²⁶ Birds do not have a *cutaneous trunci* muscle, so a panniculus response cannot be used to help localize a spinal cord lesion; however, the feather follicles contain sensory nerve fibers.³¹

Evaluation of nociception (deep pain perception) is reserved for those animals showing evidence of spinal cord disease based on abnormalities in gait, proprioception and spinal reflexes. Nociception requires cerebral perception of painful or injurious stimuli. It is important to remember that a withdrawal reflex is not an indicator of pain perception and may be elicited in an animal whose spinal cord has been transected cranial to the segment responsible for that reflex arc.^{26,40} See Chapter 8, Pain Management.

Ancillary Neurological Tests

SURVEY RADIOGRAPHY AND MYELOGRAPHY

After a thorough clinical examination, selective or survey radiography may be indicated to evaluate body systems for their contribution to clinical signs. As it is inexpensive and non-invasive, survey radiography may be one of the best screening tools to uncover a cause for neurologic disease.

Sedation or general anesthesia facilitates exact positioning to yield the best image of the desired area. Both lateral and ventrodorsal projections should be obtained, with the beam centered over the area of interest. The axial skeleton of the bird should be extended, and the spine should be made parallel to the cassette, supporting the bird's body with foam wedges if required. The most helpful spinal views include the following: cervical (lateral and ventrodorsal), thoracic (lateral), thoracolumbar (lateral and ventrodorsal), and lumbar (lateral and ventrodorsal). A fine screen and high-detail films^a should be used for spinal studies in birds.

Myelography can be performed in birds with normal patient recovery and adds another diagnostic procedure to the armamentarium of avian veterinarians. Myelography is used to identify, characterize and localize spinal cord lesions to the extramedullary or intramedullary compartments. Myelography is indicated if precise localization of a spinal cord lesion is required, such as when surgical intervention is contemplated. A contrast medium is injected into the subarachnoid space and lack of opacification around the spinal cord indicates displacement of that cord segment, preventing contrast material flow and suggesting diffuse cord swelling or a space-occupying mass compressing the cord.

The synsacrum of birds is composed of the fused lumbar and sacral vertebrae and pelvis, and necessitates thoracolumbar rather than lumbar puncture of the subarachnoid space. Another structure unique to birds is the glycogen body, which bisects the spinal cord in the lumbosacral region ventral to the synsacrum and causes a narrowing of the subarachnoid space in this region.⁵¹ It appears that injection of contrast medium into the subarachnoid space in the cerebellomedullary cistern cannot be consistently repeated and trauma to the spinal cord near the brainstem can result in death.⁵¹

A technique for administering a myelographic contrast agent, iohexol^b, in the thoracolumbar region has been described.⁵¹ The region for injection is found by placing the thumb and middle finger on the bony prominences of the ileal crests, with the index finger used to palpate to the first indentation cranial to the synsacrum. The quantity of the contrast medium needed to produce a diagnostic myelogram is 0.88 ml/kg, 4 times the 0.22 ml/kg used in mammals in most institutions.⁵¹ The use of a 27-gauge needle for this procedure is currently recommended,⁵¹ and the administration of approximately 0.5 ml/minute has been described as safe.⁵¹ Radiographs should be made within 10 minutes of the contrast

administration. Seizures, the predominant side effect noted in mammalian myelography, have not been observed in birds, even at higher doses than those recommended above. However, this does not rule out the possibility of this occurring with iohexol myelography in birds. There are some avian species in which myelography may not be possible. In duck, goose and swan skeletons, the thoracic and lumbar vertebrae have overlapping plates of bone that would prevent positioning a needle in the subarachnoid space. Potential thoracolumbar puncture sites do exist in psittacines and raptors, which are the most commonly seen patients in private practice and rehabilitation centers.

CEREBROSPINAL ANALYSIS

Cerebrospinal fluid (CSF) may confirm pathologic changes, determine the general nature of the pathologic process or reveal a specific cause of disease.^{25,64} CSF is most useful in characterizing infectious, neoplastic or inflammatory disorders of the spinal cord or brain. Ideally, this procedure should be performed prior to myelography, as contrast will affect the analysis of the fluid.

In birds, the cerebellomedullary cistern is very small, and a large venous plexus exists just ventral to it. ⁶² There is less than a 1 mm space dorsal to the cervical spinal cord in which the tip of the needle could be placed. This can result in blood-contaminated samples, lack of samples and damage to the nervous tissue. ⁵¹ The damage, which can be focal and cause acute severe hemorrhage in the subarachnoid space, can result in postanesthetic recovery problems including cardiac arrest and death. ⁵¹ Presently, it is recommended to use a 27-gauge needle for this procedure. ³⁰

How to Perform

The patient is placed in lateral recumbency with the midline of the neck parallel to the tabletop. The caudodorsal skull region is aseptically prepared. The atlanto-occipital joint is flexed at a 30° angle, and a 27-gauge hypodermic needle is placed at dorsal midline, slightly caudal to the occipital protuberance, and is directed rostrally at a 45° angle to the horizontal axis of the head. The needle is advanced through the skin slowly at 1-mm intervals until a slight change in resistance is felt. Practically, this is not always easily recognized. However, the advantage of using a hypodermic needle with a translucent hub, rather than a spinal needle with a stilette, is that an immediate "flash" of fluid will appear in the hub of the needle once the dura has been penetrated. This limits the risk of advancing the needle into parenchyma. In general, 0.1 to 0.5 ml of fluid may be collected. In small mammals, 1 ml of CSF per 5 kg body weight may be removed safely, although this has not been confirmed in birds.25

Fig 17.11 | A barred owl (*Strix varia*) under general anesthesia for an electromyographic examination.

Fig 17.12 | A concentric needle is inserted into each muscle for evaluation of the presence of a spontaneous electrical activity.

How to Interpret

The small sample volume usually obtained precludes extensive biochemical analysis, bacterial or fungal culture, and antibody titer evaluation. Color and clarity of the CSF should be evaluated immediately. Gross visual examination of normal CSF reveals a clear and colorless fluid. Blood contamination may be iatrogenic or due to a pathologic process.²⁶ Turbidity indicates leukocytosis, high protein content or both. If the sample volume is sufficient, protein content may be evaluated in addition to cytological examination. High protein concentration indicates breakdown of the blood-brain barrier or intrathecal protein synthesis. Preparation of the CSF sample by cytospin centrifugation is recommended because of the small volume and low cellularity of fluid generally recovered.26 If a cytocentrifuge is unavailable, the cells may be concentrated onto a slide by sedimentation.25 The cell concentration, population and morphology are evaluated. Relative erythrocyte and leukocyte numbers and protein concentration should be compared with those found in the peripheral blood. Reference values for leukocyte numbers and protein concentration in CSF have not been established in birds. Subjective comparison of CSF values with those of peripheral blood and consideration of parameters used in domestic animals may aid interpretation.

Meningitis caused by infectious agents generally induces a moderate increase in cell numbers and an increase in protein concentration compared with peripheral blood.^{3,26} Non-inflammatory conditions caused by degenerative disease or trauma cause a high protein concentration and a minimally increased cell count.^{25,26}

ELECTRODIAGNOSTICS

The use of electrophysiological diagnostic techniques has become a cornerstone in the investigation of neuromuscular disease in animals. Electrodiagnostic evaluation of the neuromuscular system is used as an aid in the diagnosis of disease, to assess the progress or regression of the disease, and to assess the degree of recovery. Skeletal and smooth muscle as well as the myoneural junction can be examined. Concentric needle electrodes are used to determine the spontaneous or evoked responses. They are usually 27-gauge, subcutaneous or longer, insulated needles with bare tips, which can be inserted into the muscle. A ground electrode must always be used. The patient usually has to be anesthetized for these procedures (Fig 17.11).

Electromyography

Electromyography (EMG) is the study of the electrical activity of muscle by insertion of a recording electrode into the muscle (Fig 17.12). It examines the integrity of the motor unit, which consists of the lower motor neuron and the muscle fibers that it innervates. Normal resting muscle does not show observable electrical activity once the electrode placement is stabilized and no audible signal is created. 110 Contraindications for electromyography include bleeding tendencies and unusual susceptibility to recurrent systemic infections. 61 Electrical activity demonstrated can be separated into three categories: insertional (associated with electrode movement), spontaneous (associated with resting muscle) and evoked (associated with electrical stimulation of nerves). 61

Insertional

A brief burst of electrical activity accompanies needle insertion into a normally innervated muscle. This collection of monophasic and polyphasic potentials of variable amplitude and duration ends after the needle has stopped its movement. A prolonged discharge of these potentials is sometimes subjectively considered as abnormal, as it represents cellular hyperirritability. Insertional potentials become more noticeable on the

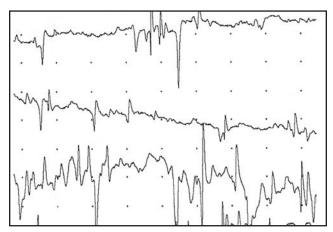

Fig 17.13 | Fibrillation potentials and positive sharp waves from a denervated muscle 5 days after brachial trauma.

fourth or fifth day after denervation and peak in intensity 8 to 10 days after denervation.²⁶ These may be decreased or absent in atrophied muscle.¹¹⁰

Spontaneous

Normally, muscles are said to be "electrically silent." Five to seven days after denervation in the dog, needle electromyography can demonstrate spontaneous, randomly occurring potentials.26 These are the action potentials of several muscle fibers due to instability in the membrane potential and are termed fibrillation potentials. The time of onset of these potentials in birds has been poorly documented, but may be earlier than seen in the dog. Fibrillation potentials can be monophasic, biphasic and, rarely, triphasic in wave form with a usual amplitude of 20 to 300 μ V and a duration of 0.5 to 5 msec (Fig 17.13), both of which decrease with cicatrization. 110 The presence of reproducible discharges in at least two different areas of muscle usually suggests lower motor neuron disease. These include diseases of the ventral horn cells, radiculopathies, plexopathies, myositis, and axonal mono- or polyneuropathies. 61 Positive sharp waves with a sawtooth appearance also are abnormal spontaneous potentials that are detected in motor unit disorders, and it has been suggested that they may precede fibrillation potentials by one or more days. 110 Complex repetitive discharges range from 50 μV to 1 mV in amplitude and up to 50 to 100 msec in duration, representing a group of muscle fibers firing in near synchrony.⁶¹ These discharges typically begin suddenly and maintain a constant firing rate, ceasing abruptly and sounding like a machine gun. 61 These complex repetitive discharges appear as a "train" of identical discharges. These discharges may occur in a variety of myopathic conditions. Needle electromyography has been used in the cat, a species susceptible to organophosphorus-induced delayed neuropathy like the bird, to monitor progression and improvement.1 This could not be repeated, though, in chickens.107 Denervation is detectable on needle electromyography in

birds. Fibrillation potentials and occasional complex repetitive discharges were seen in the wing muscles of two red-tailed hawks with traumatic brachial plexus injury. Motor unit action potentials observed in these same birds suggested that intact nerve fibers were present. ¹⁰⁸ Fibrillation potentials and positive sharp waves were detected diffusely in limb musculature of a turkey vulture with a peripheral neuropathy associated with lead toxicosis. ⁹² Spontaneous EMG also has been used to determine prognosis and to direct treatment in seven wild birds with traumatic injuries involving peripheral nerves and musculoskeletal disease. ²⁷ Widespread fibrillation potentials and lack of typical interference patterns suggested denervation in three of these seven birds that had muscle atrophy and wing paralysis or paresis.

Evoked

The M wave is an evoked potential resulting from the summation of motor unit potentials. The latency of response represents the time taken for impulse conduction from the point of stimulus to the nerve terminal, including a neuromuscular delay of about 0.5 msec, and the time taken for conduction from the end-plate region to the exploring electrode. The latency can be considered an adequate substitute for the nerve conduction velocity. The amplitude of the evoked potential is determined by the number of muscle fibers activated by nerve stimulation. In a severed motor nerve, conduction stops abruptly after about 5 to 8 days. The latency of the substitution is a severed motor nerve, conduction stops abruptly after about 5 to 8 days.

Nerve Conduction Studies

Nerve conduction studies have become a simple and reliable test of peripheral nerve function. 61 The conduction velocity is measured between the two stimulus points on the nerve, thereby eliminating the time for neuromuscular transmission and generation of muscle action potential. It is derived as the ratio between the distance between two stimulation cathodes and the corresponding latency difference. 61 The proximal stimulation site is a point just caudal to the greater trochanter of the femur, and the distal site is just caudal to the distal portion of the tibia (Fig 17.14). At each site, the cathode is placed distal to the anode. The indifferent electrode is placed subcutaneously over the midtarsometatarsus region. The active electrode is placed subcutaneously on the caudal portion of the hypotarsus just distal to the tarsometatarsal joint overlying the digital abductor muscles.10 Similar electrode configurations are needed for evaluation of the wing nerves (Fig 17.15). The ground electrode is placed subcutaneously between the distal stimulation site and the recording site. This technique has been described in detail for two avian orders.27

Axonal damage or dysfunction will usually result in loss of amplitude, whereas demyelination leads to prolonga-

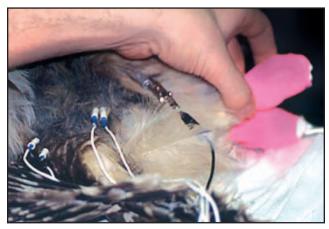

Fig 17.14 | Needle setup for evaluation of a tibial nerve conduction velocity in a barred owl.

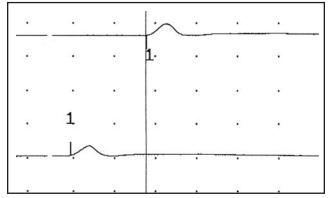

Fig 17.16 | A reduced nerve conduction velocity is demonstrated after stimulation of the proximal portions (top trace) of the tibial nerve and the distal portions (lower trace). The waveforms (M wave) demonstrated here are typical.

Fig 17.15 | Needle setup for evaluation of an ulnar nerve conduction velocity in a rhea.

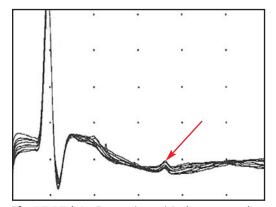

Fig 17.17 | An F wave (arrow) is demonstrated after the M wave and the stimulation artifact.

tion of conduction time (Fig 17.16).⁶¹ Reference ranges for the motor nerve conduction velocities of the ulnar nerve and the tibial nerve in neurologically normal barred owls and rheas have been established.²⁷ Based upon these ranges, a turkey vulture with lead toxicosis was shown to have decreased sciatic-tibial nerve conduction velocity compatible with a demyelinating neuropathy.⁹² Peripheral nerve histopathology confirmed this finding.

Effect of Temperature

A linear relation normally exists between motor nerve conduction velocity and temperature of the peripheral nerve segment within physiological limits.⁶⁷

Effects of Age

Immature animals have slower motor nerve conduction velocity than do adults.²⁶

The F Wave

Measurement of the F wave can help in the assessing of motor conduction along the most proximal segment of the nerve. This is because it results from the backfiring of antidromically activated ventral horn cells. It can supplement the conventional nerve conduction studies, especially in polyneuropathies where delay of the F wave can markedly exceed the normal range. It occurs after the M response, its initiating electrical stimulation having traveled toward the spinal cord before it returns to activate distal muscles (Fig 17.17). Studies of the F wave can help in the characterization of polyneuropathies and, more specifically, with those that are prominently proximal, such as radiculopathies.⁶¹ Such studies have been attempted in normal birds, but as yet a reference range has not been established for clinical application.²⁷

Repetitive Stimulation

Repeated supramaximal stimulation should create repeatable, identical action potentials in the normal patient. Any evident incremental or decremental response may have physiological significance. Any defect in the neuro-muscular transmission will usually produce a maximal drop in amplitude between the first and second responses of a train, followed by further decline up to the fourth or fifth potential. Examples of these disorders would be myasthenia gravis in humans and companion animals and botulism in all species. Repetitive stimulation has been performed in normal birds to

establish reference ranges for clinical application.²⁷ The techniques were easily performed and demonstrated 22% alteration in potential amplitude.²⁷

MUSCLE BIOPSY

Muscle biopsy is indicated to confirm, define and possibly provide a cause for motor unit disease. 19,88 Biopsy techniques are well established in several mammalian species, but are not known for avian patients. The muscle selected for biopsy should be one that is clinically affected with the disease process. In acute disease, a severely affected muscle is selected. With chronic disease, a muscle demonstrating only moderate changes is the best choice. The muscle should be easily accessible and identifiable so that minimal postoperative discomfort is created. Ideally, the muscle chosen for biopsy would be one for which normal fiber type, distribution and size are known. This is not available for most avian patients. Studies of muscle fiber types have been done in chickens. 16

SCINTIGRAPHY

Nuclear imaging or scintigraphy is a non-invasive method for evaluation of soft tissue and osseous structures associated with the nervous system. 112 The technique involves intravenous administration of a small amount of a gamma-emitting radionuclide alone or tagged to some other compound that will allow it to accumulate in certain tissues and exclude it from other tissues. A gamma camera is used to record the amount of radiation emitted from the body and to create images of the distribution of the radionuclide throughout the patient's body. Technetium-99m (99mTC) is used most often, as it has a short half-life (approximately 6 hours) and emits pure gamma radiation. Because the level of radiation is extremely low, its use carries minimal risk for the patient and personnel involved with the procedure. Nuclear scans do not provide detailed anatomic imaging, but do have the potential to provide functional information when used with a digital image processor.

Scintigraphic imaging of the brain has been done in human medicine since 1960.²⁶ In recent years, cranial scintigraphic imaging has been replaced by computed tomography (CT) and magnetic resonance imaging (MRI), but is still useful where these modalities are considered too expensive or are not available. Bone scanning is particularly useful in identifying spinal abnormalities in birds.²⁶ Superimposition of osseous structures (ribs, synsacrum) in survey radiographs makes identification of spinal fractures and early vertebral osteomyelitis difficult. In a study of 12 birds with thoracic or pelvic limb paresis, bone scanning identified 100% of the lesions identified on survey radiographs.⁷⁵ In addition,

several lesions not identified on survey radiographs, including fractures and early osteomyelitis, were identified by bone scanning. These pathologic lesions were confirmed by the results of necropsy. Basilic vein administration of the radionuclide was found to be superior to medial metatarsal vein administration. This is possibly because the renal portal system provided high uptake of radionuclide by the liver and kidney and obscured visualization of the spine after medial metatarsal vein administration.⁷⁵

COMPUTED TOMOGRAPHY

Computed tomography imaging requires general anesthesia, uses ionizing radiation and is somewhat costly to perform. The CT scan uses x-rays and computer technology to create cross-sectional images of the patient. ^{54,68} Regions of the vertebral column and the skull are evaluated for abnormalities in CNS soft tissue or its protective skeleton. Computed tomography provides superior soft tissue imaging with no superimposition of structures compared with conventional radiography. ^{77,86} With contrast administration, soft tissue structures are better visualized, especially where there is increased blood flow. ^{86,99}

The greatest value of CT lies in its ability to reveal changes in bony tissues and to provide greater detail of osseous structures than conventional radiography. Slices are most commonly created every 2 to 3 mm in birds. ⁸⁶ Although these slices may seem very close together, focal lesions may still be missed. Decreasing slice thickness to 2 mm decreases image quality, but may increase sensitivity for small lesions. Images also can be reformatted by the computer to provide images in configurations other than a transverse plane.

Computed tomography has been used to document topographic anatomy of the golden eagle and African grey parrot, 77,86 and it also has been used to specifically demonstrate brain and skull anatomy of the crested breed of the domestic duck (*Anas platyrhynchos*). 12 Computed tomography has been used with some success to locate intracranial lesions in birds, although it was only 80% sensitive. 58,99 A postmortem CT scan was used to identify spinal cord compression in a juvenile penguin (*Aptenodytes patagonicus*) that was euthanized because of an inability to stand despite 6 weeks of medical therapy; 38 radiographs at presentation had failed to identify any spinal abnormalities. Results of necropsy confirmed intervertebral disc rupture and vertebral body displacement.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) uses a pulsating external magnetic field and produces radiofrequency signals that are used to generate images.^{26,112} Soft tissue con-

trast of the CNS is excellent with MRI, which also provides the spatial orientation of anatomic structures. ^{26,112} This modality also will help to differentiate central nervous system gray and white matter.

The advantages of MRI compared with CT include the ability to image the cranial brainstem, without artifact, in the caudal fossa of the skull, the increase in soft tissue detail, the creation of images in various planes and the lack of ionizing radiation.98 However, MRI does not allow a satisfactory depiction of aerated bones in some avian skulls.12 One main disadvantage of MRI besides the expense, as with CT, is the requirement for general anesthesia, as chemical sedation is not adequate to obtain satisfactory images. It also is necessary to obtain screening radiographs of birds before performing MRI evaluations to rule out the presence of metallic foreign bodies.98 Avian patients will frequently chew on their cages, etc, and small metal fragments may contaminate commercial feed. Ferrous metal demonstrates susceptibility to the magnetic field and can move within the body.98

In a study of normal MRI brain anatomy of pigeons, imaging required approximately 20 minutes, and transverse images were created every 3 mm.98 A 1.5 Tesla magnet and a human knee surface coil were used. Lesions may be missed because of this distance between slices. This imaging technique also was used in a clinical case in an attempt to identify the cause of seizure activity in a mealy Amazon parrot (Amazona farinosa).98 Without contrast enhancement the lesions were not visualized; however, after the use of contrast material (gadopentate dimeglumine^c 0.25 mmol/kg IV) perivascular infiltrates were identified, showing disruption of the blood-brain barrier. Because the contrast is eliminated through the kidneys, postcontrast uric acid levels have been compared to precontrast levels to monitor for potential renal toxicity in birds; however, no significant changes have been found.98 Further, after contrast medium-enhanced MRI studies in birds, recovery has been uneventful and the birds have had normal excreta, appetites and attitudes.98 Magnetic resonance imaging also has been used to evaluate the cranium of domestic ducks.¹³ MRI images were recorded using a relatively large slice thickness of 5 mm, which can lead to difficulty in interpreting scans of small volumes.

Intracranial Disease

CLINICAL SIGNS

Intracranial CNS structures include the forebrain (telencephalon), thalamus (diencephalon), midbrain (mesencephalon), pons (metencephalon), medulla oblongata

(myelencephalon) and the cerebellum. The midbrain, pons and medulla make up the brainstem and are associated with the majority of the cranial nerves. Disease affecting the intracranial CNS may be focal or diffuse. If it is focal, specific deficits may be identified relating to dysfunction of the area affected. The various syndromes and specific signs are described in Table 17.3.

Seizures

Definitions and Classifications

A seizure is a sudden, uncontrolled, transient alteration in behavior characterized by a change in motor activity, consciousness, sensation or autonomic function.²⁸ It is due to a synchronizing abnormal paroxysmal electrical discharge from the brain. *A generalized seizure* is manifested by symmetrical and synchronous clinical signs, which are classically tonic-clonic motions often accompanied by complete loss of consciousness.²⁸ *A focal*

Table 17.3 | Intracranial Lesion Localization and Clinical Signs 93

Clinical Syndrome/ Lesion Localization	Characteristics of the Location	Specific Clinical Signs
Cerebrum	Damage to cere- brum affects intellec- tual, learned and sensory activities (vision, hearing, touch, pain)	i. Altered mental state ii. Seizures iii. Behavioral change iv. Pleurothotonus and adversion v. Head pressing vi. Central blindness
Diencephalon	Damage affects autonomic visceral functions and endocrine regulation	i. Altered mental state ii. Seizures iii. Behavioral change iv. Endocrine disturbances v. Abnormalities of temperature
Midbrain	Damage affects con- trol of alert status, as well as CN III and CN IV function	i. Altered mental state ii. Opisthotonus iii. Contralateral paresis iv. Ipsilateral CN III dysfunction (mydriasis/ventrolateral strabismus) v. Contralateral CN IV dysfunction (dorsomedial strabismus)
Pons and Medulla	Damage affects multiple cranial nerves (V-XII) as well as cardiorespiratory centers	i. Altered mental state ii. Ipsilateral paresis iii. Irregular respiration iv. Ipsilateral CN V dysfunction (decreased beak strength, decreased facial sensation) v. Ipsilateral CN VI dysfunction (third eyelid protrusion and medial strabismus) vi. Ipsilateral CN VII dysfunction (decreased tone in facial musculature, decreased taste, decreased lacrimation) vii. Ipsilateral CN VIII damage (ipsilateral CN VIII damage (ipsilateral CN VIII damage (dysphagia, regurgitation, tongue deviation, inspiratory dyspnea)
Cerebellum	Damage affects coordinating and reinforcing actions	i. Normal mental status and behavior ii. Normal strength iii. Opisthotonus iv. Dysmetric ataxia v. Head (intention) tremors

seizure is manifested initially by focal signs that may secondarily become generalized.

Treatment

- 1. Address the underlying cause.
- 2. Control seizure activity with diazepam (0.5-1.0 mg/kg IV or IO).²⁸ This can be repeated two to three times if necessary.
- 3. If diazepam does not stop the activity, administer phenobarbital (1-2 mg/kg IV/IO or IM q 6-12 h to effect).²⁸
- 4. Gaseous anesthesia may be warranted in seizuring birds to allow diagnostic sampling and investigation.
- Convert to oral phenobarbital maintenance therapy within 48 hours (1-10 mg/kg PO q 12 h is standard therapy).²⁸
- 6. Primidone may be an alternative anticonvulsant, although its active compound is phenobarbital. Primidone use (125 mg/day in water source) has been reported in an Amazon parrot.⁵²
- 7. Adjust to lowest dosage required to control seizure activity.

Head Tilt and Nystagmus

Definitions and Classifications

A head tilt is due to asymmetrical disease of the vestibular system (Fig 17.18). The vestibular system comprises the peripheral component, which is the vestibular portion of CN VIII arising in the inner ear from the semicircular canals and the central component, which is the nuclei of CN VIII in the medulla.28 A further central component of this system is the flocculonodular lobe of the cerebellum. Head tilts are usually toward the side of the disease with peripheral vestibular dysfunction, but toward any side with central dysfunction. Nystagmus that is pathological is described as jerky eye movements with two obvious phases; slow and fast. The predominant direction of the eye movements, seen at rest, can be horizontal, rotational or vertical. Nystagmus also can be positional, which means that it is induced by a change in position of the head. With horizontal nystagmus, the fast phase is usually away from the side of the lesion. Vertical and positional nystagmus can indicate that the lesion is central rather than peripheral. All other directions can occur with both peripheral or central lesion localizations.

Treatment

- 1. Address the underlying cause and tailor therapy to the specific etiology.
- 2. Provide supportive care to maintain nutritional and fluid demands.

Tremors and Involuntary Movements

Definitions and Classifications

Head and or body tremors may occur with activity and

Fig 17.18 | A lovebird (Agapornis roseicollis) demonstrates a right-sided head tilt caused by an ipsilateral loss of muscle tone due to peripheral vestibular disease.

appear worse with movement such as eating or drinking. These are called intention tremors and are the cardinal sign of cerebellar disease of any underlying etiology. Generalized body tremors that occur mainly at rest could result from a multifocal or diffuse lesion localization. This may be a disease affecting the meninges, nerve roots, peripheral nerves or muscles. Systemic diseases including electrolyte imbalances, liver and renal disease, and hypoglycemia can cause generalized tremors as can primary neurologic diseases.

Treatment

- 1. Address the underlying cause.
- 2. Attempt treatment with oral anticonvulsant therapy as above.
- 3. Attempt treatment with anti-inflammatory doses of glucocorticoids.
- 4. Provide supportive care to maintain nutritional and fluid demands.

Depression/Stupor/Coma

Definitions and Classifications

Depression represents a reduced mental state, although one which responds to external stimuli. Depression does not necessarily indicate primary neurologic disease. Stupor is a state of unconsciousness from which the bird can be roused by stimulation with a noxious stimulus (Fig 17.19). Coma is a state of unconsciousness from which the bird cannot be roused by noxious stimuli.

Treatment

- 1. Address the underlying cause.
- 2. Provide supportive care to maintain nutritional and fluid demands.
- 3. Address ventilatory needs.
- 4. Address excretion needs and keep clean.

Fig 17.19 | A painted bunting (*Passerina ciris*) with profound stupor due to pesticide toxicosis.

Fig 17.20 | A gross pathological specimen from an African grey parrot (*Psittacus erithacus*) with cerebral disease due to hydrocephalus.

DIFFERENTIAL DIAGNOSIS OF INTRACRANIAL DISEASE (Table 17.4)

Degenerative

Lysosomal Storage Disease

Gangliosidosis18,60

Neurolipofuscinosis53

Avian Vacuolar Myelinopathy⁷¹

This disease more commonly causes spinal and neuromuscular signs, but intracranial signs have been reported.

Anomalous

Hydrocephalus¹⁰⁰

Dilated ventricles can be a congenital lesion as well as a postinflammatory consequence (Fig 17.20).

Metabolic

Hepatic Encephalopathy^{15,29}

Clinical signs included depression, ataxia and blindness.

Hypoglycemia¹⁵

Seizure activity may occur when the glucose levels drop below 100 mg/dl.

Hypocalcemia

Serum calcium levels below 6.0 mg/dl with concentrations as low as 2.4 mg/dl have been reported to cause opisthotonus (Fig 17.21), tonic extension of the limbs and convulsions.¹⁵

Neoplasia^{100,113}

In a retrospective study of 996 budgerigars (*Melopsittacus undulatus*), 14 (1%) intracranial tumors were detected.¹¹³ Tumors of the ependyma (6), choroid plexus (1), adenohypophysis (6) and one unclassified tumor were found. In this study 87% of the birds were male,

Table 17.4 | Differential Diagnosis of Intracranial Disease

	Pinciciniai Piagnosis oi inii aciamai Piscasc
Mechanism of Disease	Specific Diseases
Degenerative	i. Lysosomal storage disease - Gangliosidosis/Neurolipofuscinosis ii. Avian vacuolar myelinopathy
Anomalous	i. Hydrocephalus
Metabolic	i. Hepatic encephalopathy ii. Hypoglycemia iii. Hypocalcemia
Neoplastic	i. Glial tumors/Ependymoma/Choroid plexus papillomas/Adenomas/Adenocarcinomas/ Lymphosarcoma/Lipomas
Nutritional	i. Pyridoxine deficiency ii. Vitamin E deficiency
Inflammatory	i. Viral encephalitis - Proventricular dilatation disease/Avian paramyxovirus type 1 (Newcastle disease)/Polyomavirus/WEE and EEE/West Nile virus/Avian influenza virus/Herpes (duck viral enteritis) ii. Bacterial encephalitis - Salmonella/Pasteurella/Streptococcus/Enterococcus/Chlamydophila/Listeria iii. Verminous encephalitis - Chandlerella/Baylisascaris/(fluke/Schistosomiasis) iv. Trichomonas/Protozoal encephalitis - Toxoplasmosis/Leucocytozoonosis/Sarcocystis v. Fungal encephalitis - Mucormycosis vi. Prion - Spongiform encephalopathy
Idiopathic	i. Idiopathic epilepsy
Toxicity	i. Lead ii. Zinc iii. Organophosphates and carbamates
Trauma	i. Head trauma
Vascular	i. Atherosclerosis

indicating a possible sex predisposition, as there were equal numbers of males and females in the study. Typically, neoplasia is a necropsy diagnosis, but it may be found antemortem with a CT or MRI scan. Glial cell tumors, choroid plexus papillomas, adenomas, adenocarcinomas and lymphosarcomas have all been reported as individual primary brain tumors.¹⁵

Intracranial Lipomas

Four birds in a flock of 125 purebred crested ducks (*Anas platyrhynchos*) had cerebellar signs of unknown

Fig 17.21 | A young cockatiel (Nymphicus hollandicus) demonstrates the marked dorsiflexion of the neck seen with opisthotonus.

Fig 17.22 | A pigeon (Columba livia) with paramyxovirus infection of the central nervous system demonstrates profound torticollis of the neck.

etiology. 14 Gross necropsy of the euthanized ducks revealed yellow intracranial masses in the brain of each. Histologically, these masses were intracranial lipomas consisting of fatty tissue separated into lobules by connective tissue. These lipomas were similar to those recorded in other animals and humans.14

Nutritional

Pyridoxine (Vitamin B₆) Deficiency¹⁵

Vitamin E Deficiency (Nutritional Encephalomalacia)⁶

The recommended dietary level of vitamin E for domestic poultry is 10 to 25 IU/kg feed dry matter (DM), but this is not known for many other birds. Clinical signs are commonly seen in young chicks (2-6 weeks old) and include ataxia, head retraction and "cycling" with legs.6 This has become known as crazy chick disease. 66 Gross and histological lesions of encephalomalacia are primarily found in the cerebellum, with evidence of ischemic necrosis of the cerebellar cortex and white matter, capillary thrombi, hemorrhages and malacia.

Inflammatory

Viral Encephalitis

Avian Paramyxovirus Type 1 (Newcastle Disease) causes a non-suppurative encephalomyelitis and has been reported to cause head shaking, head tremors, head tilt, circling and torticollis (Fig 17.22).869 Infection is usually reported in juvenile wild birds, racing pigeons and domestic poultry.^{57,69} The virus will commonly cause motor dysfunction and so is discussed below.

Avian Polyomavirus (APV), also known as budgerigar fledgling disease, is a member of the family Papovaviridae.⁷² Polyomavirus infection in psittacine birds may be subclinical or may present as a fatal, acute, multisystemic disease.72 Although observed more frequently in budgerigars (Melopsittacus undulatus), APV infection may result in death of both juvenile and adult non-budgerigar

psittacine species.⁷² Viral inclusions have been found in brain tissue, however, reports of virus-induced neurologic disease are rare.72 Tremors of the head, neck and limbs, incoordination and ataxia have been described in nestling budgerigars with APV infection. Approximately 10% of susceptible neonates exhibited neurologic signs.⁷² In addition, an adult Moluccan cockatoo (Cacatua moluccensis) with APV infection exhibited inability to perch properly and had a slight torticollis that progressed to a semicomatose state.72 Neurologic deterioration was observed over a 2-day period following a 1-week history of illness. Body tremors and unsteadiness on the perch were signs documented in a Ducorps's cockatoo (Cacatua ducorps) with concurrent APV and psittacine beak and feather disease virus (PBFDV).72 PBFDV (circovirus) infection is often associated with clinical evidence of acquired immunodeficiency, leading to a variety of secondary or opportunistic infections.72

Proventricular Dilation Disease (PDD) is a progressive, variably contagious and often fatal disease of psittacine birds, which is presumed to be caused by an unidentified neurotropic virus.¹⁷ The disease was first recognized in macaws in the late 1970s in the USA and is now known to have a worldwide distribution affecting more than 50 species of psittacine birds. 17 Neurologic clinical signs include ataxia, tremors and seizures. Definitive diagnosis in live and dead birds is based on demonstration of characteristic lymphoplasmacytic infiltrates within autonomic nerves and ganglia at various levels of the digestive tract. 17,48

Equine Encephalitis - Viral infections have been reported in commercial, domestic, and free-living flocks of passerines and Columbiformes for several decades.96 Most infections are attributed to eastern equine encephalitis (EEE), but several outbreaks of western equine encephalitis (WEE) have been documented.96 Many types of birds are natural hosts of EEE and WEE viruses.96 The diseases are caused by an alpha virus in

the arbovirus group/family, and are transmitted through the bites of mosquitoes.

Specific signs of WEE and EEE have been vague. In 1991, the first confirmed outbreak of EEE was reported in ratites, specifically emus (*Dromiceius novaebollandiae*) in southeastern Louisiana. This outbreak coincided with unseasonably heavy rainfall, an abundance of arthropod vectors and close proximity to reservoir host species. Affected emus exhibit variable signs, becoming very drowsy and depressed, reluctant to stand up, trembling, often remaining sitting, and developing an S-shaped cervical curvature. Aroused sick birds are ataxic with leg weakness. Both infections can progress to cause paralysis and death. 114

Diagnosis is confirmed by isolation of the virus from the brains of birds that die. Serum antibody titers for EEE, WEE and Venezuelan equine encephalitis exposure can be evaluated by hemagglutination inhibition. ⁹⁶ Recently, an immunohistochemistry technique for confirmatory diagnosis of EEE infection in birds has been developed. ¹²¹ Treatment has been supportive, consisting of oral electrolytes and broad-spectrum antibiotics. ⁹⁶ Protection of commercial emu flocks may be attempted by a routine vaccination schedule for both EEE and WEE. Vaccine efficacy recently has been proven in emus, and it currently is the only protective action that exists, other than mosquito control. ^{96,114}

West Nile Virus (WNV) emerged in the northeastern USA in the summer of 1999 causing death to thousands of wild and zoo birds. 41,106 Previously this infection has been reported around the Mediterranean basin. 81 It is a mosquito-borne flavivirus that is endemic in Africa and Asia, occurring sporadically in temperate regions of Europe. 106 It has been shown to cause a diffuse encephalitis and has been recovered from the brains of birds in winter, long after the mosquito vectors ceased to be active, suggesting a prey-to-predator mode of transmission. 41 Live and inactivated vaccines for protection against WNV recently have been evaluated in young domestic geese with initial promising results. 78

Avian Influenza Virus has been reported to cause 75 to 100% mortality in birds within 10 days of infection. 91 Depression and neurologic dysfunction were common clinical manifestations of the disease. 91 These signs include attenuated motor functions, such as paresis to paralysis, vestibular dysfunction as indicated by torticollis and nystagmus, and general behavior aberrations. 91

Herpes (Duck Viral Enteritis) causes photophobia, ataxia, seizures and penile prolapse.¹⁵

Bunyavirus¹⁰⁹ rarely causes clinical disease after trans-

mission of the virus from mosquitoes.

Bacterial Encephalitis

Listeria monocytogenes causes intracranial infections of birds resulting in opisthotonus, ataxia, and torticollis.¹⁵

Chlamydophila psittaci will occasionally cause neurologic signs in birds following acute respiratory or gastrointestinal disease.¹⁵

Abscesses, granulomas, encephalitis and meningitis has been reported to be due to *Salmonella typhimurium*,⁵⁵ *Pasteurella multocida* (fowl cholera),⁵⁰ Lancefield group D *Streptococcus* sp.,^{24,47} and *Enterococcus* sp. (neonatal multifocal encephalomalacia with sepsis).^{24,44}

Verminous Encephalitis

Chandlerella quiscali is a filariid nematode of grackles that has been reported to cause cerebrospinal nematodiasis in emus.¹⁵ Clinical signs in the young include torticollis, ataxia, recumbency and death.

Baylisascaris procyonis - The common raccoon ascarid is known to cause life-threatening visceral, cerebral and ocular larva migrans in birds in North America. ^{23,32} Infected asymptomatic raccoons can harbor a large number of worms and shed large numbers of infective eggs into the environment. ²³ Affected birds can develop ataxia and dysmetria that progresses to inability to stand, with severe torticollis and a head tilt. ²³

Trichomonas gallinae causes disease in the domestic pigeon and birds that feed on pigeons such as eagles, falcons and hawks; it has been responsible for avian enteric trichomoniasis.⁸⁹ Caseous masses in the roof of the mouth may extend to involve the brain.

Schistosomiasis causing granulomatous encephalitis has been reported in swans.¹⁵

Protozoal Encephalitis

Toxoplasma gondii, a cyst-forming coccidium, is not frequently identified as pathogenic in captive birds. Asymptomatic infection with this parasite is reportedly common.74 Outbreaks of toxoplasmosis have been reported worldwide in chickens, and in passerine and psittacine birds and birds exhibited in zoos. 74,122 Naturally occurring infections have been diagnosed in chickens, ducks and many wild birds. 122 Because toxoplasmosis is a zoonotic disease, the source of the infection should be determined, if possible, to prevent infection of humans. Household cats should be tested. Common clinical signs of T. gondii infection in avian species include anorexia, blindness, head tilt, circling and ataxia.74,122 Canaries (Serinus canaria) may be susceptible to a form of toxoplasmosis of the central nervous system and eyes that differs from the acute form seen in other species.74

Partridges (Perdix perdix) have been reported to be more susceptible to toxoplasmosis than other gallinaceous birds.104

Serological antibody titers have been reported (latex agglutination test) for infected birds, but have not been helpful. A single titer can rarely specifically diagnose the disease when the birds have been previously exposed. 42 Treatment of suspected cases and all in-contact birds with trimethoprim 0.08 g/ml H₂O and sulfadiazine 0.04 g/ml in water for 3 weeks has been advised, but eradication from a captive flock may be difficult. 122

Trichomonas gallinae⁸⁹

Leucocytozoonosis95

Sarcocystis spp. have been reported to cause toxoplasma-like infections of birds with a non-suppurative meningoencephalitis.49 Infection has been reported in over 60 species of birds, with Old World psittacines apparently more susceptible (see Fig 17.25).15

This disease has been reported in 53 capercaillies (Tetrao urogallus) examined at necropsy in Sweden and one capercaillie from Finland. 34,49 Protozoa were mainly confined to the brain, but systemic disease is common.³⁴ Little is known about sarcocystosis of birds in general. In North America, Sarcocystis falcatula is the most pathogenic and well-defined species among birds, with schizonts persisting in the tissues for up to 5.5 months. 15,49 The predominant lesion in fatal S. falcatula infection is pneumonia, however, Sarcocystis-associated encephalitis has been described in a golden eagle (Aquila chrysaetos) and in a straw-necked ibis (Carphibis spinicollis) in the USA. 35,49

Fungal Encephalitis

Mucormycosis is a rare infection in birds.84 The order Mucorales includes a number of saprophytic fungi that have been mentioned as possible etiologic agents of meningoencephalitis in birds.84

Spongiform Encephalopathy

Three cases of a spongiform encephalopathy of unknown etiology have been reported in ostriches (Strutbio camelus) from two zoos in northwestern Germany.63 The birds were euthanized after showing progressive ataxia and uncoordinated feeding behavior. The lesions identified by light microscopy were similar to those of prion-induced transmissible encephalopathies in mammals and had gray matter vacuolation. However, a toxic or nutritional etiology could not be ruled out.63

Idiopathic

Epilepsy

Intermittent seizures with no other abnormality can indicate idiopathic disease, especially if there is a long his-

tory of seizures. 100 In chickens, epilepsy has been found to have genetic basis. 100 Idiopathic epilepsy also may be acquired as a result of a cerebral insult and residual brain damage.100

Toxicity

Lead¹⁰⁰/Zinc⁷³

Caged birds that eat their cage wire can become intoxicated if the wire is high in zinc content. A new wire fence syndrome has been reported in emus.11 The birds gnaw away at their cage made of zinc material and eventually ingest so much that toxicity occurs. Some galvanized coatings contain as much as 99.9% zinc, but galvanized wire also may contain lead. The white rust associated with galvanized wire also is toxic.11 Waterfowl may be exposed to elevated zinc concentrations through ingestion of contaminated vegetation and sediments due to the recently approved zinc-coated iron shot used for waterfowl hunting in the USA.73

Seizures can be a common clinical sign of zinc toxicity, in conjunction with paresis, polyuria/polydipsia, weight loss, anemia and gastrointestinal abnormalities. Sudden death has been reported in orange-bellied parrots (Neophema chrysogaster) due to zinc toxicoses, however, it was thought to be a result of the birds colliding with walls or structures in the aviary, causing head trauma.55 Serum concentrations of zinc can be used to confirm the diagnosis and should be compared to normal birds as controls. Syringes with rubber stoppers should be avoided as this may be a source of zinc contamination.11 In general, zinc levels greater than 2 ppm in emu are considered diagnostic for toxicity. Tissue levels can be evaluated postmortem in suspicious cases.55 Published reference values of zinc levels in tissues of normal birds are as follows: macaws, 75 µg/g (tissue unspecified);55 cockatiels (Nymphicus hollandicus), 59 μ g/g in the kidneys, 72 μ g/g in the liver and 94 μ g/g in the pancreas;55 goldeneye ducks (Bucephala islandica), 35.9 μg/g in the liver;⁵⁵ and peach-faced lovebirds (Agapornis roseicollis), 21 and 33 μg/g in the liver. 55 Treatment is discussed in Chapter 31, Implications of Toxins in Clinical Disorders.

Organophosphates, Carbamates and Pesticides

There are over 80 different registered organophosphates and carbamates in the USA, with both classes being acetylcholinesterase inhibitors that bind to and subsequently inactivate acetylcholinesterase, causing an accumulation of acetylcholine at the postsynaptic receptors. 15 Birds are 10 to 20 times more susceptible to these inhibitors than mammals. Acute intoxications can cause seizure activity. Exposure to carbamate insecticides can be detected using brain cholinesterase reactivation techniques. 5,56,105

Fig 17.23 | A rose-crowned fruit dove (Ptilinopus regina) is examined after head trauma, demonstrating superficial skin lesions.

Trauma

Head Trauma (Fig 17.23)^{15,53}

Vascular

Atherosclerosis

Atherosclerosis occurs with some degree of frequency in birds. ¹⁵ Often this can cause acute death, but can cause sudden onset blindness, ataxia, paresis and seizures. ¹⁵ Clinical signs may be from the cerebrovascular accidents, and MRI or CT may be useful in their diagnosis. ¹⁵ See Chapter 12, Evaluating and Treating the Cardiovascular System.

Spinal and Neuromuscular Disease

CLINICAL SIGNS (Table 17.5)

Monoparesis/Monoplegia/Hemiparesis/ Hemiplegia

Definitions and Classifications

Paresis indicates the presence of reduced motor function in the limbs. The suffix "-plegia" indicates the complete loss of motor function. The prefix mono- indicates the involvement of just one limb (Fig 17.24) and the prefix hemi- indicates the involvement of both limbs on one side of the body with normality on the contralateral side. Monoparesis sometimes may be expressed as a "clenched" claw (Fig 17.25).

Treatment

- 1. Specific treatment of the underlying etiology.
- 2. Skin care for recumbent birds or those that are dragging their limbs.
- 3. Physiotherapy.
- 4. Supportive care if unable to eat and drink.

Tetraparesis/Paraparesis/Paralysis

Definitions and Classifications

The prefix tetra- indicates the involvement of all four limbs. Tetraplegia is very rare due to the negative effect such a lesion would have on the respiratory capabilities of the patient. The prefix para- indicates the involvement of just the pelvic limbs, and paralysis or the equivalent paraplegia indicates complete loss of motor movement in the pelvic limbs (Fig 17.26).

Treatment

- 1. Specific treatment of the underlying etiology.
- Skin care for recumbent birds or those that are dragging their limbs.
- 3. Physiotherapy.
- 4. Supportive care if unable to eat and drink.

Ataxia

Definitions and Classifications

Ataxia indicates an uncoordinated gait and does not necessitate an impairment of motor function, but there may be a concurrent paresis. Ataxia is often due to spinal disease, but may be due to either vestibular or cerebellar disease. There will be no motor dysfunction in the case of pure cerebellar ataxia.

Table 17.5 | Spinal Lesion Localization and Clinical Signs⁹³

141410 1210	Spiriar Lesion Localiza	mon and eminear signs
Clinical Syndrome/ Lesion Localization	Characteristics of the Location	Specific Clinical Signs
